CARTWRIGHT LECTURES,*

ON THE

PHYSIOLOGICAL ANTAGONISM BETWEEN MEDICINES, AND BETWEEN REMEDIES AND DISEASES.

BY ROBERTS BARTHOLOW, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

(Special report for THE MEDICAL RECORD.)

LECTURE VI.

THE ANTAGONISM BETWEEN REMEDIES AND DISEASES.

Mr. President and Gentlemen—As we have seen that the treatment of local affections is governed to a large extent by the principle of antagonisms, let us now inquire whether this principle is equally applicable to the treatment of constitutional states. An investigation in this direction will show, I think, that there are proper antagonists to inflammation, to fever, and to the diatheses and cachexiæ, and that our most successful treatment of these conditions is based substantially upon the doctrine of antagonisms.

First, as to inflammation. This is a process which, assuming no points that remain unsettled, may be defined to consist in a dilatation (paresis) of the vessel-walls, followed by stasis of the blood; in an increase of the number and modification of the character of the white blood-corpuscles, and their migration from the vessels into the surrounding tissues, in a simultaneous diapedesis of the red corpuscles; in an increase and change of character of the fibrin and albumen of the blood, and their exudation within the area of inflammation; in the diffusion of the salts of the serum, especially of the chlorides, into the inflamed parts; in an increased multiplication of the cellular elements of the tissues, in consequence of the increased pabulum furnished them; and in a breaking up, disassociation and granular degeneration of the anatomical elements of the inflamed tissues. In addition to the local process, there is a general febrile state of the system which is characterized by increased temperature, increased heart-action, and diminished arterial tension.

REMEDIES AGAINST INFLAMMATION.

There is no one remedy capable of antagonizing such a complexus of symptoms; but we have those in our possession which may counteract the various stages of the process as they successively arise.

ANTAGONISTS TO THE FIRST STAGE OF INFLAMMATION.

As any agent to be of service in the commencement of an inflammation must act upon the corpuscular elements of the blood, as well as the contractility of the vessels, we look for remedies having these effects, and find that there are two of the utmost value, and there are others of secondary importance in this connection. Quinia and morphia, if administered at the right moment, will, I believe, often suppress a commencing inflammation. There is need of facts to support this statement; but I am fully convinced that the existence of the antagonism between these agents and the initial stage of inflammation will in time be incontrovertibly established. Now as to the nature of this antagonism. Since morphia, as we have seen, has the power of increasing the vascular tension and of checking all vital processes, the explanation of its action at once becomes apparent. Quinia, however, possesses a wider range of action. It would take too much time to speak in any detail of the exhaustive modern researches in regard to its physiological effects, and I must content myself, consequently, with the barest statement of the main facts. Its power of arresting the movements and other vital actions of the white corpuscles has been proved to be due to its action, as a poison, in destroying protoplasm and the minutest forms of life, and for the demonstration of this property we are mainly indebted to Prof. Binz, of Bonn. In order to act efficiently as a protoplasmic poison it is necessary, as we would naturally suppose, that it should be given in large doses. In addition, quinia, as has been shown by Binz and other investigators, has the property of diminishing the oxidizing function of the blood; and Ranke, Kerner, and Strassburg have demonstrated that it also has the effect of reducing by fully one-half the excretion of urea and uric acid. As the amount of urea excreted shows to what extent the oxidation of the nitrogenous tissues is going on, it is obvious that quinia must have the effect of checking this oxidation. Hence, it follows this agent antagonizes the increased heat-production, the migration and subsequent multiplication of the white corpuscles and proliferation of the protoplasm of the tissues; while morphia, by raising the vascular tonus and diminishing the heart's action, tends to remove the congestion.

The three remedies whose action is of secondary importance in the first stage of inflammation are, digitalis, aconite, and veratrum viride. Although they all possess the power of lowering the circulation, they differ in the modes by which they accomplish this object. Digitalis has the effect of slowing the heart, while it energizes its movements and increases the vascular tension; but any effect that it may have over the movements and changes of the protoplasm is secondary to its action on the vascular tension. Its influence on temperature is very evident; but at the same time it ranks far below quinia as an antipyretic. One great objection to the use of digitalis in the early stage of inflammation is the slowness of its action, since it takes from five to ten hours, after the primary disturbance caused by it on the digestive organs, for its characteristic physiological effects to appear. Then, as the slow diffusion of the active constituents into the blood is only equalled by their tardy excretion, it follows that digitalis cannot be used effectively in this connection.

Aconite has the effect of diminishing the power of

* Of the Alumni Association of the College of Physicians and Surgeons, New York.

the heart, and although it also lowers arterial tension, the amount of blood reaching the seat of inflammation is reduced by it. Besides, it lessens oxidation by diminishing the work of the lungs, and reduces temperature, partly because less blood is distributed when the heart is working under its influence, and partly because the supply of oxygen reaching the tissues is less. Hence, aconite is especially indicated when the general arterial tension is high and hæmatosis is active.

Veratrum viride resembles aconite very strongly in its action, but it has a more decided effect upon the heart and proportionally less influence over the lungs. Its agency in checking inflammation, like that of aconite, depends on the reduction of the quantity of blood supplied to the inflamed area, and the diminution of oxidation which it produces. The good effects of digitalis, aconite, and veratrum viride cease with the occurrence of exudation, because new conditions then arise over which they have no control whatever.

ANTAGONISTS TO THE SECOND STAGE OF INFLAMMATION.

The antagonists to the second stage of inflammation must, of necessity, have the power of preventing or removing the products of inflammation; and such agents are found in quinia, chloral, and the alkalies. Quinia, it may be stated, ceases to be of service when the exudate has actually formed; but chloral is especially adapted to this stage, since it has the effect of reducing the temperature, dissolving the exudations, and quieting restlessness and delirium. With the exception of its solvent action on exudations, these properties of chloral are disputed by none. The experimental evidence on which the existence of this solvent action rests, however, seems to be quite conclusive; while the clinical evidence, although limited and difficult to define, would appear to be decidedly confirmatory of the experimental. Since, however, the points of contact between chloral in the blood and the exudation in an inflamed area are necessarily small, it follows that it must be more effective when it is administered before the final stasis occurs. An important contraindication against the use of chloral ought not to be overlooked, viz.: the paralyzing effect of this agent upon a weak heart. When given for the purposes indicated above the dose should be small and not repeated at shorter intervals than every two hours; while the tendency to cardiac depression which may result from it can be successfully combated by the joint administration with it of atropia, which does not diminish the efficacy of the remedy in the direction for which it is used.

It seems to be a fact, now perfectly well established by clinical experience, that the alkalies—and especially the potash, ammonia, and lithia salts—have the power, by increasing the alkalinity of the blood, of checking the formation of exudations, and causing their solution, to a greater or less extent, after they have already formed. This method of treating inflammations was practised, on a large scale, by the late Dr. J. Hughes Bennett, and his exceptionally extensive experience on this point entitles his declarations to special consideration. Ammonia being more diffusible than the other alkalies, it has always seemed to me to be more effective, and it is best given in the form of the carbonate, dissolved in the officinal liquor ammonia acetatis.

ANTAGONISTS TO THE THIRD STAGE OF INFLAMMATION.

When the exudation is undergoing solution, preparatory to absorption and extrusion, digitalis and quinia again come into use, since they seem to give tone to vessels long in a paretic condition and to favor the transformation and elimination of the inflammatory products. As the action of the heart, in consequence of the more or less long-continued strain to which it has been subjected, is apt to be irritable, quick, and wanting in energy, digitalis is probably of more service that the quinia.

THE ANTAGONISTS OF FEVER.

The discussion of the nature of fever has been very fruitful in many respects during the past four years; but it has not settled the question, and we are still in the dark in regard to its essence, while the existence of a heat-regulating centre is both maintained and denied. No single source of heat, it would seem, can be alone concerned in the production of fever, and the truth, probably lies, to a greater or less extent, in all of the theories that have been propounded. The means for reducing fever-heat which we now possess operate both by acting the source of heat-production and by facilitating its radiation from the body. In the first group are those which check or retard these processes on which the formation of heat depends, known as antipyretics, and besides the antipyretics proper there are numerous remedies (the paralyzers especially) which diminish heat-production among the other toxic phenomena which they produce.

The first of the agents affecting heat-production is repose, and I believe I was the first, or at least among the first, to show that if rabbits, pigeons, and other small animals are so fettered as to be kept immovable for some time, the temperature of their bodies declines. Hence, remedies which have the power of suspending muscular activity cause a reduction of temperature which is quite independent of any influence they may exert on heat-production, and it is obvious that conclusions drawn from observations in which this cause of lowered temperature is not taken into consideration, must be defective and misleading.

The most important medicinal agents which affect heat-production are quinia, salicylic acid, resorcin, chloral, digitalis, aconite, and veratrum viride. Besides such remedies as these, all the agents which depress the functions of respiration and circulation diminish heat-production to a greater or less extent. Liebermeister, after an exhaustive examination of the relative merits of different agents, including cold baths and all the methods of hydrotherapy, holds that quinia is entitled to the first place as an antipyretic, and his opinion is but an echo of the general sentiment among more enlightened medical thinkers. The utility of this remedy consists in the possession of remarkable power to reduce temperature, conjoined with a minimum of evil effects. In addition to what has already been said in regard to the antipyretic qualities of quinia, I need now merely state that the reduction of temperature caused by it is the result of its influence over the vital activity of protoplasm, and over the so-called oxidizing action of the blood. As to the quantity of the remedy required, not less than twenty grains can have any distinct antipyretic effect, and our German *confrères* are in the habit of giving twenty, thirty, forty, and even sixty grains, and repeating it as often as may be necessary to keep the temperature down to the proper line. It is true that in malarial diseases much smaller doses may diminish fever, but here another element enters the problem. That quinia exercises the same curative influence over febrile diseases, such

as typhoid, which it does over malarial diseases, cannot be maintained for a moment. The effect that it has on the course of fever is due purely to its antipyretic property; while on malarial diseases its action is specific and particular.

Salicylic acid, like quinia, does not affect the normal temperature, though it has a powerful effect on the temperature of fever. It has also many other analogies with quinia, but it is necessary to give it in considerably larger doses. The quantity required to produce a decided antipyretic effect is not less than sixty grains, and eighty, or even one hundred and twenty grains, are sometimes demanded. The duration of the decline of temperature which follows the profuse diaphoresis that usually occurs, is about six hours, and this furnishes the measure of time for its repetition. For the reduction of the temperature in fevers in general, it is not nearly of as much value as quinia; but in acute rheumatism its antipyretic power, which would seem to be the secret of its curative effect in that disease, renders it highly useful.

Resorcin is a new remedy which is likely to be of service as an antipyretic as well as an antiseptic. The dose as an antipyretic is about sixty grains, and as it has no irritant properties, it may be used hypodermetically without danger of inflammation and abscess. At first it produces quickened action of the heart, with flushing of the face and a sense of warmth and precordial oppression; after which profuse perspiration follows, and with this comes the decline in temperature, the latter usually being very decided.

While digitalis is both less efficient and less prompt in reducing febrile temperature than quinia, and is apt to produce gastro-intestinal disturbance, and while its use is contraindicated when there is weakness of the heart from granular degeneration of its muscular fibre, there are, nevertheless, symptoms of the febrile state against which this agent can be resorted to with signal advantage. In the exanthematous fevers, and especially scarlatina, digitalis antagonizes the symptoms most active in bringing about a fatal result, viz.: a weak heart, low vascular tension, accelerated circulation, high temperature, and deficient urinary secretion.

Aconite, although its antipyretic effect is less certain and decided than that of digitalis, diminishes the activity of the cardiac motor apparatus, and reduces the vascular tension; and hence it antagonizes the febrile condition that is associated with rapid, powerful, and irregular action of the heart, and high arterial tension. It is rather in opposition to certain symptoms of the febrile state than as an antipyretic that aconite is useful. Whenever high fever is due to sthenic inflammation it may reduce the temperature by operating upon its source, and the same is also true of veratrum viride, which, like aconite, has little value purely as an antipyretic.

The most efficient remedy in reducing the high temperature of the essential fevers is cold, and certainly no antagonism could be more exact than that between cold and heat. When the blood is heated above the normal by the febrile process in the system, the action of the heart is augmented in a corresponding degree, and when the surface blood is repeatedly cooled, the whole quantity of blood in the body at length becomes lowered in temperature, and as a result the heart-beat soon grows less frequent. The result is the same in whatever manner the cold is applied, whether by means of the cold bath, the cold pack, the rectal injection of ice-water, or the external application of ice-bags. With the decline of the body-heat, all these changes resulting from elevated temperature cease. In sunstroke, or thermal fever, and in certain cases of acute rheumatism, it is seen how quickly hyperpyrexia may destroy life, and how life may be preserved under circumstances of the most imminent danger is demonstrated when in this condition of hyperpyrexia the abnormal heat is removed by the prompt application of cold. That the treatment of fevers—of typhoid, especially—has been greatly advanced by the method of hydrotherapy seems hardly to admit of question. The treatment by cold baths is particularly adapted to those fevers in which the high temperature is the dominant fact; but hydrotherapy becomes of less and less service the more the morbid condition is determined by some special poison acting on particular organs. Typhoid fever represents one group, and small-pox the other group of febrile affections.

ANTAGONISTS TO THE ANIMAL POISONS, HYDROPHOBIA, SYPHILIS, THE DIATHESES AND THE CACHEXIÆ.

The third and last division of maladies against which we may direct our antagonists are the animal poisons, hydrophobia, syphilis, the diatheses and the cachexiæ. Woorara, as I have previously mentioned, has seemed in two instances to antagonize the convulsive phenomena of hydrophobia. To this statement may be added the remarkable case recently treated by pilocarpin, in which the tragic death in a wild delirium may be explained by the accidental moral causes, the spasms having subsided under the action of the remedy in eliminating the poison by means of the profuse salivary flow excited by it. The results obtained by Dr. Guttman in the treatment of diphtheria with pilocarpin are very striking. Of eighty-one cases thus treated by him, not one proved fatal, and he assumed that the free salivary discharge occasioned softening and detachment of the false membrane. There must, however, be some other antagonistic influence at work in order to produce such uniformly good results, and it is very desirable to have further experience in regard to the use of pilocarpin in diphtheria; but it should not be forgotten that this remedy has a depressing effect on the heart, and may, therefore, only add to the gravity of the disease, which also has a marked tendency to paralyze the heart.

MERCURY AND SYPHILIS.

Probably no fact in therapeutics is better established than the curative effect of mercury in constitutional syphilis. Although some resemblance may be admitted to exist in the action of both agents upon the system, they are such decided antagonists that they cannot exist in the same organ or tissue—one must displace the other. Iodide of potassium, on the other hand, is a chemical antidote rather than a physiological antagonist to syphilis.

THE LESSONS TO BE LEARNED FROM THE WHOLE SUBJECT.

Taking, finally, a comprehensive view of the subject treated in the preceding lectures, what are the lessons to be learned? It is obvious, I think, that the only rule which we apply in therapeutics, as far as any rule is applicable, is the rule or principle of antagonisms. In the case of the treatment of poisons the antagonism is direct, the two opposing agents counterbalancing each other until the natural powers accomplish the elimination of the toxic agent. When a poison enters the blood a series of disturbances follows, which is due to its presence, to its action on the tissues for which it has a special affinity,

and to the efforts made by nature toward its elimination. The antagonist pursues a similar course, but affects the particular tissue for which it has an affinity in an opposite manner, and thus prevents the impairment of function, which would otherwise result in death, until elimination occurs.

(Having reviewed the methods in which antagonisms are exerted in the treatment of diseases of particular organs, in inflammation and in fever, the lecturer said that the right use of remedies, in accordance with the law of antagonisms, required an accurate knowledge of physiological therapeutics, and that he feared that the same interest was not exhibited in the study of modern therapeutics as in other departments of medical science and art, there being still present the notion that observation and experience should be the sole foundations for the construction of a therapeutical science. He then concluded as follows:) While the notions of the actions and uses of drugs engendered by experience and observations are constantly changing, the deductions of experiments have the same value as the same methods in the other experimental sciences. To this end we should direct our best efforts, and rest satisfied with no less certainty than that which belongs to the exact sciences, until we have attained to the degree of perfection that, the disease being given, the remedy follows.

CHLORAL HYDRATE.

By H. H. KANE, M.D.,
NEW YORK.

Part II.

DEATHS FROM CHLORAL.

(Continued from p. 705, vol. xviii.)

The history of the following interesting case has been kindly sent me by Dr. D. Tod Gilliam, of Columbus, Ohio:

E. R. P——, aged 33 years, medium stature, full habit, sanguine temperament, by occupation commission merchant, came under treatment for incipient *mania a potu*, September 24, 1877. He had habitually enjoyed good health, and his occupation secured to him much out-door exercise. He had been a total abstainer for four years; this because of his known tendency to go to extremes in drinking when once started. He never drank habitually, but paroxysmally, ending his debauches only with the wreck of purse and person. On the 20th of September, 1877, he went to Chicago on an excursion, and on account of some slight indisposition was induced to take brandy. From this time on he drank furiously, returning to this city on the 24th inst., when I saw him and prescribed:

℞. Chloral hydrat.,
Potass. bromid .... āā ʒiv.
Aquæ,
Syr. zinziber..... āā ℥ij.
M. Sig.—One tablespoonful every three hours, or, if need be, not to exceed three doses, at intervals of two hours, to secure quietude.

Perfect quietude, abstinence from spirits, and liquid nourishment seasoned, when appropriate, with cavenne pepper, were also enjoined.

September 25th.—Had been drinking and in almost continuous motion; face flushed, eyes suffused, pulse quickened and voluminous, speech stammering and excited. Naturally very affable, he was courteous to those around him, but would not brook restraint. Chloral suspended and morphia substituted.

September 26th.—No obvious change except an exacerbation in the foregoing symptoms. Is fully alive to his condition, and promises, with tears, to restrain himself. Complains of gastric distress, but does not vomit. Will not take nourishment. Has had snatches of sleep, but awakens in a panic, in which he attacks his attendants, but desists on being spoken to. Think I ordered sol. citrat. potass. for gastric trouble, and insisted on his being kept under perfect restraint. Morphia continued, as it seemed to be more potent for good.

September 27th.—Patient had defied restraint and was still drinking. Ordered a discontinuance of medicine unless provision could be made to keep him from drink. During the day he procured and took one bottle of Seltzer's aperient without my knowledge; in the evening he took about half of a second bottle. At 9 P.M. he was given a dose of the original prescription of chloral and bromide. At 11 P.M. he went to the water-closet, where he remained until 1 A.M., purging violently. He now returned to his room, much exhausted, and was given another dose of the chloral. He fell into a sleep, as also did the attendant. The latter awoke at 4 A.M., and upon going to the bed of our patient discovered that he could not arouse him, and that he had also ceased to breathe. I was sent for and found him dead. The appearance was of one in natural repose; the eyes were closed, the face retained its color, the features were calm and life-like, and *the body heat above the normal*. His friends declined to have a *post-mortem*.

The minor details of treatment are omitted for obvious reasons, but I have given you all that could, in any way, affect or modify the use of the chloral. The rise in body heat, after death, struck me at the time as being anomalous in death from chloral. It was too conspicuous to be mistaken, and was remarked on by those present.

Dr. A. P. Hayne, of the Home for Inebriates, San Francisco, Cal., writes me of two cases of sudden death after the use of chloral. In the first case there was enlargement of the heart. There was no autopsy in either case. "In the first it was my idea that there was a clot in the heart, and in the latter (there was convulsions) that the convulsions of alcoholism had arrested the circulation." The dose was in both cases twenty grains. Both patients had, on previous occasions, taken thirty-grain doses without any ill effect. An interesting pamphlet upon the subject of alcoholism has been sent me by Dr. Hayne,* and will be spoken of more fully when we come to discuss the treatment of delirium tremens by chloral.

Dr. Roswell Park, of Chicago, Ill., writes me of the case of an Irish cook, aged forty years, who, through the stupidity or carelessness of the nurse, was allowed to help herself to about 480 grains of potassium bromide and 300 grains of chloral. She sank into a stupor and died. The pupils were *widely dilated*, a very unusual occurrence, and possibly due to the large amount of potassium bromide taken.

Dr. H. W. Boyd, of Chicago, Ill., relates the following, which is undoubtedly an instance of cumulative action resulting in sudden paralysis of the heart:

"I had a patient afflicted with delirium, the result

* Alcoholism: Its Patho-Anatomical Conditions, Symptomatology, and Treatment. By Arthur P. Hayne, A.M., M.D., San Francisco, Cal.

of chronic alcoholism, who took ʒ iv. inside of twenty-four hours. He was a powerful man, over six feet in height, 190 pounds weight, aged thirty years, a blacksmith by trade. He had been on a terrible spree for a month, and was trying to stop. He could not sleep. I gave him a prescription of ʒ ij. hyd. chloral, ʒ ss. syr. tolu, one teaspoonful at once, and another in three hours if he was not asleep. He kept it up every three hours, got the prescription repeated, and kept it up for twenty-four hours, and did not sleep, but said he felt great relief from it. He went on a spree again in a few days, and in a week or two attempted to stop again. He did not come to see me, but simply got the prescription repeated, and took it as before, without producing sleep. This was repeated with similar results for three or four of his periodical sprees, until one night, after he had taken the chloral a little more freely and a little oftener, he could not sleep, and attempted to get up and put on his clothes; he fell backward on the bed, dead. Whether the chloral caused death in this case, or whether he had congestion of the brain from some other cause, I do not know. I think the chloral got the credit of killing him."

Dr. T. B Camden, of Weston, W. Va., writes me of the case of a gentleman whose friends attempted to "taper him" off, and gave him an unknown quantity of chloral in some wine. He died very suddenly, *just after sneezing.*

Dr. M. B. Mosser, of Mechanicsburg, Pa., writes me of the following cases:

A young man, aged 29 years, very intemperate, was advised by a physician to take chloral hydrate for obstinate insomnia and restlessness. He did so, and continued its use for about a year. Leaving home on a debauch, he was found, several days after, in a hotel twenty miles from home, having died from a supposed overdose of chloral, part of which was found on his person. No autopsy.

Patrick H——, aged 60 years, nervous temperament, was of spare habit, very intemperate, and by occupation a porter, was attacked by delirium tremens. Dr. N—— was summoned to his relief, and after prescribing and administering the usual remedies for three days without much effect, he concluded to administer hydrate of chloral for the relief of the insomnia then present, and which had kept up for seventy-two hours in the most obstinate manner. Twenty-grain doses of chloral were ordered every two hours until sleep was produced. But a single dose was given, when I was called upon by Dr. N—— to visit the case in consultation with him, and, greatly to the surprise of both, found the patient in a state of coma, or bearing all the indications of syncope (collapse): hurried respiration, fluttering heart, feeble pulse, low temperature, and an absolute inability to move hand or foot—in a word, was unconscious, in which condition he died soon after; *opinion* (quietly): *that there was too much chloral in the case.* No autopsy.

Dr. Madison Marsh,* of Louisiana, relates several cases of death, one from forty-five grains in three doses; fatal collapse followed fifteen minutes after the last dose. One death occurred during labor. In the next number of the same journal three cases are given where death occurred from unknown quantity in intemperate persons. All these cases are very loosely reported, not even the symptoms being given, so that it is difficult to say what really was the cause of death.

* Med. and Surg. Reporter, Jan. 16, 1875.

Death from thirty grains, in the case of a drunkard, is reported by Schwaighofer,* of Vienna.

Dr. E. Spottswood † reports two cases of death in drunkards. These cases are of but little value, owing to the loose way in which they are reported.

Fürstner,‡ of Vienna, believes that these cases of death in delirium tremens are due to the paralyzing action of alcohol and chloral on the centres in the medulla, for, in several instances where he has been enabled to hold an autopsy, absolutely no disease of the heart was found. Before death the pulse was small, frequent, and irregular, and the heart-sounds faint. In such condition of pulse and heart, therefore, he believes that chloral should not be used, more especially if there is less restlessness than is usually found.

Dr. James Perrigo, Med. Department of Bishop's Coll., Montreal, Canada, sends me the details of a case of death from chloral in delirium tremens, occurring in a London hospital some years ago. The case was one of delirium tremens following a compound fracture of the tibia and fibula. Chloral hydrate was ordered in ten-grain doses every few hours. The next day the man was dead asleep, but on the following morning he was thoroughly comatose and died. There is, in my mind, considerable question in this, as in many of the other cases, as to whether death was really due to the drug. Dr. Perrigo does not remember the details, and there was no autopsy. It was the opinion of the attending surgeon that chloral caused the fatal result, but he also believed that the house surgeon gave it in larger doses and oftener than he had ordered.

Dr. Perrigo mentions another case, that of a druggist who took an unknown quantity of the drug to relieve the pain of neuralgia. He died. There was no autopsy.

In the following cases an autopsy was held:

Dr. Long,§ of Geneva, was called to see a neuropathic patient who had taken 186 grains of chloral hydrate on his own responsibility. Respiration stertorous, face pale, skin cool, pulse strong, vibrating, and at fifty pulsations per minute. Complete relaxation. Abolition of direct and reflex sensitiveness. Pupils contracted and motionless. Conjunctiva insensible. Emetics, friction, sinapisms to body and limbs. Pulse suddenly stopped and then started again. Electricity to chest. Death two hours after taking the drug.

Autopsy, fifty-six hours after death.—No fluid in brain or membranes. Heart arrested in diastole. Clots in both cavities. Left pleura adherent. Mucous membrane of stomach hyperæmic, also ecchymotic in places. No erosions or ulceration. Bladder full of urine.

On chemical analysis the stomach was found to contain a considerable quantity of chloral hydrate. Urine from bladder contained none.

Dr. Pedro Molina Flores, of Guatemala, Central America, writes: "I know of but one case where chloral hydrate caused death. The amount taken is not known, nor were his symptoms noted, as he was seen by no physician after he took the drug. On the 14th of August, 1869, the autopsy of Joseph Viscarra was made. The superficial parts of the neck, back, and other parts of the body were spotted purplish-blue. On opening the cavity of the cranium the hairy scalp was found injected with blood. The men-

‡ Ibid., June 8, 1878.
§ Gaz. des hôpitaux, 1875, p. 141.

inges, cerebrum, and cerebellum were congested, and gave off a strong alcoholic odor. The other organs presented nothing abnormal."

Dr. Loose, of Bremen, has kindly sent me one of his articles,* which contains a report of the following case: A custom-house officer, aged twenty-three years, took about 120 grains of chloral, which he procured by means of a prescription written by himself. He retired at nine P.M., and was found dead the next morning. The autopsy showed pleuritic adhesions on the right side. Right lung markedly, left lung slightly œdematous. There was found a subpleural effusion of blood as large as a hazel-nut. There was slight mitral insufficiency. The blood, when tested three days later, showed no signs of chloroform.

Dr. B. W. Richardson, in his report on chloral hydrate, before the British Medical Association,† says:

"The post-mortem appearances were noticed after a poisonous dose. The vessels of the brain are found turgid with blood. The blood is fluid, and coagulation is delayed (in a bird to a period of three minutes), but afterward a loose coagulum is formed. The color of the brain-substance is a darkish pink. The muscles generally contain a large quantity of blood, which exudes from them on incision freely. This blood coagulates with moderate firmness. Immediately after death all motion of the heart is found to be arrested. The organ is left with blood on both sides, but with more in the right than the left side. The color of the blood on the two sides is natural, and the coagulation of this blood is moderately firm. The other organs of the body are natural."

Two cases of fatal poisoning are related by Kirn ‡ in his article on the habitual use of chloral. Other deaths from chloral are reported as follows: *Boston M. and S. Journ.*, Feb. 9, 1871; Ibid., April 1, 1880; and *Phila. Med. Times*, 1878, p. 82 (Carroll).

Francis Ogston, Jr., M.D., has kindly sent me the reprint of an article § of his from the *Edinburgh Med. Jour.*, October, 1878:

"A farmer in the neighborhood of Aberdeen, who had been in the habit of using chloral for some time, was one day found dead in a field. Some slight bruises led to a legal examination. The autopsy, made thirty-six hours after death, revealed:

"*Externally.*—The joints rigid; the pupils of the eyes normal in size; the face, front of neck, top of chest, and back parts purple. Several excoriations, with effusion of clotted blood, on the backs of both hands, and on the left leg and foot. Well-marked goose-skin on the outer sides of the thighs. The penis retracted.

Internally.—The scalp congested; the cerebral sinuses filled with clotted blood; the blood-vessels on the surface of the brain full of blood; the arachnoid thickened and of a gelatinous appearance; a large quantity of clear, watery fluid under the arachnoid and in the ventricles of the brain; the brain apparently somewhat wasted, but otherwise natural, no great amount of bloody spots being noted. Nothing unusual in the mouth, pharynx, and œsophagus, except that the last was thrown into folds, and its mucous membrane somewhat softened; but the parts at the top of the windpipe were œdematous, and the mucous membrane of the windpipe was injected and dark red in color. The lungs were deeply congested and œdematous. The heart was healthy, but its right cavities contained ten fluid ounces of blood, and its left three fluid ounces, the blood in both cavities being dark, partly fluid and partly in dark, firm clots. The gall-bladder was distended with bile. The liver, spleen, and kidneys were much congested, the liver and kidneys being slightly fatty, and the spleen being softened. The urinary bladder was full of urine of a pale color. Stomach containing a brownish fluid, having a peculiar odor, and solid particles (starchy). The mucous membrane of the great cul-de-sac of the stomach of an uniform brown-black color, with several patches the size of a sixpence, of bright red punctiform extravasation. The blackening extended in streaks toward the smaller end of the stomach, following the course of the blood-vessel, and the rugæ of the stomach were greatly swollen and œdematous, and of a red color, which near the larger end of the organ was dark brown-red, and became brighter toward the small end, where it was scarlet-red. Several patches of punctiform ecchymosis were also observed in the middle portion of the stomach. The intestines showed no marked abnormal appearances. The blood throughout the body was of a dark cherry-red color, giving the muscles a brighter hue than usual.

"From these appearances my colleague and I gave it as our opinion that death had been probably caused by one of the narcotico-acrid class of poisons, but stated that a chemical examination was necessary to determine the point with certainty, and that with this in view we had preserved some of the viscera, blood, and urine.

"An order to make the necessary analysis was sent me subsequently, and I proceeded to act on it along with my father, Professor Ogston, with the results which shall be described hereafter.

"In the meantime I shall recapitulate the points which seem to me characteristic of poisoning by chloral hydrate: 1, the blood-vessels of the membranes of the brain were full of blood; 2, the sinuses contained clotted blood; 3, the arachnoid was œdematous; and, 4, under it and in the ventricles of the brain clear serum was found in considerable quantity; 5, the brain-substance appeared somewhat shrunken, but no unusual number of bloody points was noted; 6, the œsophagus was slightly contracted and rugose, and its mucous membrane was softened; 7, the parts at the top of the larynx were œdematous, and the mucous membrane of the trachea showed fine injection of its blood-vessels; 8, the lungs were œdematous, and deeply congested; 9, the right cavities of the heart were filled with blood (ten fluid ounces), and the left were comparatively empty (three fluid ounces); 10, the blood in the heart was partly in firm black clots and partly fluid. Here and throughout the body it became, on exposure, of a dark cherry-red color, somewhat darker than that found after death by cold; 11, the urinary bladder was filled with urine of a pale color, its walls normal in color; 12, the gall-bladder was distended with bile; 13, the liver was loaded with dark blood; 14, the kidneys were loaded with dark blood; 15, the spleen was somewhat soft, and loaded with dark blood; 16, the stomach showed remarkably the action of the poison, as has been already fully described; 17, the great and small intestines showed nothing unusual."

Dr. Ogston applied the stale ammonium sulphide test to the contents of the stomach and obtained distinct evidence of chloral. He says of this new test:

"The addition of stale sulphide of ammonium to a

§ A Case of Poisoning by Chloral Hydrate, introducing a New Test.

solution of chloral hydrate of moderate strength, say ten grains to the drachm (the strength of the British syrupus chloralis hydrastis), causes, in a short time (*not immediately*), the colorless liquid to assume a slight orange-yellow color, the liquid remaining clear; on letting it stand, the color gradually deepens to a brown, and now a cloudiness comes over it, which in about half an hour, or perhaps longer, is deposited as an amorphous precipitate of a brown color, and which appears to consist of sulphur.

"While the change of color is going on and the brownness appears in place of the orange, a gas is given off of a most offensive smell, apparently a mixture of chloroform and hydrogen sulphide, with something in addition, in such quantity as to fill a large room in a few minutes.

"In order to find out the smallest quantity of chloral hydrate which would give a reaction with ammonium sulphide,

"(*a*) I dissolved 1 gramme of it in 100 c.c. of water, took 1 c.c. of the solution and added 1 c.c. of ammonium sulphide, when the solution became of a canary yellow color, passing through orange-yellow to brown in the course of about six hours, letting fall a slight brown precipitate and giving off a characteristic smell.

"(*b*) I then took 10 c.c. of the above one per cent. solution, which I put into 100 c.c. of water, and, on adding 1 c.c. of ammonium sulphide to 1 c.c. of this solution, I got in about half an hour a slight straw color which had deepened to a pale orange color in twelve hours, giving off no smell.

"(*c*) Lastly, I took 1 c.c. of the solution *a*, which I added to 100 c.c. of water. Of this solution I took 1 c.c., and added 1 c.c. of ammonium sulphide, and, after standing for eighteen hours, the liquid had changed to an exceedingly faint straw color.

"Thus, 1 c.c. of *a* solution (0.01 gramme of chloral hydrate) gave the brown color, the precipitate, and the smell.

"One c.c. of the *b* solution (0·001 gramme) gave an orange color, but neither precipitate nor smell.

"One c.c. of the *c* solution (0·0001 gramme) gave a very faint straw color.

"The first and second of these results are, I think, sufficient to establish the presence of chloral hydrate; the third I should hardly trust to, as the reaction was so faint, though I verified it by repetition of the experiment.

"I may further state, that the similarity of the reaction of ammonium sulphide with chloral hydrate to that with antimony salts suggests a caution in accepting the orange coloration alone as a certain test for either poison. Antimony, on the one hand, may be known by the orange precipitate thrown down by the addition of an acid, which does not follow when it is chloral hydrate which is present; and chloral hydrate, on the other, by the fact that the orange color deepens, on standing, to a dull brown.

"In conclusion, chloral hydrate alone seems to give this reaction with ammonium sulphide, for I have submitted many of the substances of similar chemical construction to the test without any such result following. Among those were chloroform, chloric ether, formic acid, etc."

A very interesting paper by Falck, referred to by Dr. Ogston, on a toxicological study of chloral hydrate may be found in *Eulenberg's Vierteljahrsschrift für Gerichtliche Medicin* for October, 1877.

The conclusions to be drawn from a study of these cases will be given in a subsequent article.

191 WEST TENTH STREET, NEW YORK.

REMOVAL OF UTERUS

AND BOTH OVARIES, BY ABDOMINAL SECTION—MYO-FIBROMA.

BY CHAS. K. BRIDDON, M.D.,

SURGEON TO THE PRESBYTERIAN HOSPITAL, NEW YORK.

IN response to a telegraphic communication which I received December 1, 1880, I visited West Winsted, Conn., on the 3d, for the purpose of performing the operation of ovariotomy. Finding, on my arrival there, that the patient resided fifteen miles distant, at New Boston, in the State of Massachusetts, I left Winsted for that point on the morning of the 4th, in company with Drs. Steele and Welch, and arriving at our point of destination, I was introduced to Dr. Bushnell and his patient, Mrs. Carrie Lewis.

Previous history.—She is forty-seven years old; married; sterile; comes of a long-lived, healthy family, and she herself enjoyed exceptionally good health until between three and four years ago, when she began to notice an increase in the dimensions of her abdomen. It was, however, for some time regarded as unimportant, and as probably connected with the anticipated menopause, though she had always been, and is still regular, never having been troubled with dysmenorrhœa, menorrhagia, or metrorrhagia. The swelling gradually increased, and for the last two years has given her very considerable trouble; in fact, its bulk has made it burdensome for her to get about, and has caused so much physical suffering, that, with the consent and approval of her medical advisers, she has determined to run the risk of its removal.

Present condition.—She is a remarkably fine woman, and in pretty good condition; her hair is tinged with gray, face ruddy, and nothing in it that would appear to indicate the existence of ovarian trouble—no "facies ovariana;" body tolerably well nourished. Her abdomen is distended to its utmost, and stands out prominent in front. The tumor appears to be solid, smooth, and even in its contour, and reaches as high as the ensiform cartilage; per vaginam, it can only be obscurely felt in the *cul-de-sac*: the cervix lies high up, and in close approximation with the symphysis. Measurements as follows: circumference, on level with umbilicus, 38½ inches; from umbilicus to right anterior superior spinal process, 7¼ inches; from the same point to left anterior superior spinal process, 9½ inches; and from ensiform process to pubis, 17¼ inches.

I expressed the opinion that the trouble was not ovarian—at all events, not cystic; that it was probably a subperitoneal fibroid, and it was determined to commence with an explorative incision. The operation was begun at half-past nine, in the presence of Drs. Steele, Bushnell, Welch, Crozier, and Hurlburt. The spray was used, and, in fact, the whole proceeding was carried out with strict observance of the antiseptic principle. When the patient was fully under the influence of ether, a short incision was made in the median line, and midway between the umbilicus and pubis. After exposing the tumor, it was noted that it had not the appearance of a uterine fibro-cyst. It was of a light pearly hue, and to the touch was solid. To further determine this point, a moderate sized curved trocar was plunged into its centre, or it would be more correct to say, that an attempt was made to do so, for the dense, resisting character of it prevented the introduction of the instrument deeper than about an inch and a half. The removal of the canula was followed by quite an

alarming venous hemorrhage, which was arrested by plugging with sponge, and to hold the plug in position it was necessary to transfix it and the adjacent portion of tumor with a ligature, which was tied over the sponge.

It was now found that there were no adhesions, and that the tumor was uterine. I also found that I could isolate and surround the pedicle which was formed by the vagina and lateral ligaments, and I conceived it to be for the best interests of the woman to remove the whole. To do this it was necessary to carry the abdominal incision upward to a point midway between the umbilicus and the ensiform cartilage, which enabled us, with a little effort, to lift the mass outside. The tumor was marked on its surface by large venous canals, quite as large as the index finger, and the pedicle was made up mainly of vessels equally ugly in appearance. The Pampiniform plexuses in the broad ligaments, tortuous in form, were dilated into enormous vascular channels.

I commenced ligaturing these ligaments by introducing needles charged with the strongest plaited and thoroughly carbolized silk ligatures beneath the veins, and then tying them firmly above the free border of the ligament. Ligatures were then passed, taking up the structures between the veins and the vagina. I then transfixed the vagina, and tied on either side again above the free border of the broad ligament. These last ligatures were passed immediately below the os. After all vascular connection between the tumor and its sources of supply were thus cut off, I proceeded to remove the mass. Care was taken to leave enough stump to secure against the retraction of any portion of the pedicle through the nooses of the ligatures, and as a further security against this, a small portion of the os was left in the stump, so that it was almost impossible for it to escape from the embrace of the ligatures. In separating the tumor, of course, there was a deluge of blood from the mass itself, but none of this entered the abdominal cavity, which was protected all around the pedicle by linen compresses wet with tepid carbolized water. From the stump there was no hemorrhage; in fact, notwithstanding the very vascular character of the pedicle, save the small loss from the abdominal incision, the operation was almost bloodless as regarded the patient; in other words, the proceeding produced but little change in the tension of her arterial system, most of what was lost belonging to the tumor. The pulse of the patient and the ruddy appearance of her lips bore evidence to these facts.

Small cysts were found in the ovaries, and it was deemed prudent to remove them both. All the ligatures were brought out of the lower end of the wound. I should have cut them off short, but there were so many of them that I considered some suppuration as inevitable, and preferred to have an open track along which it could escape, and I should have passed them through the vagina, but that canal was so shortened by the ligatures passed through it that I feared I might wound the rectum in making the attempt. I introduced a drainage-tube of large diameter, which was fixed in the lower angle, the wound was closed with twenty silver wire sutures, and covered with protective and antiseptic gauze.

After the completion of the operation the patient's pulse was very good, she looked well, and before I left the house, half an hour afterward, she had come from under the influence of ether, presented scarcely any evidences of shock, and spoke to me cheerfully and full of hope.

I received written or telegraphic communications every day from the physicians in attendance; for the first few days they were of the most encouraging character, and then changes of pulse and temperature that betokened disaster, and though the death, which occurred on the 9th, was attributed to septicæmia, I have strong doubts as to whether it was not mainly owing to deferred shock, and will give the following extracts from communications to substantiate that view. The operation was done on December 4th. In a letter dated December 5th, "suffered very little from shock, and nothing from the effects of ether; passed a comfortable night. Temperature, 100°. Pulse, 115."

December 6th.—"Slept well during the night. Pulse rose from 120 to 140 in the evening, and in the same time the temperature rose to 102°."

December 7th.—"Restless during part of night; is much weaker. Temperature, 102°. Pulse, 140. Some discharge from drainage-tube."

December 8th.—"Condition about the same; extremities cold; skin dark colored. Temperature, 102°. Pulse, 150."

December 9th.—"Breathing irregular; partially unconscious. Pulse, 160. Temperature, 102⅘°. Died at 6 P.M."

At no time was there any marked abdominal tenderness, and very slight tension, and no chills were noted at any time.

The tumor, when drained of blood, weighed seventeen pounds and a half; its circumference was twenty-eight inches; its surface was channelled by grooves three-fourths of an inch in diameter, marking the site of veins; on one side of the section of its neck was a small opening which would not admit the little finger; on slitting this up it was found to lead into a bicornate cavity, representing that of the body of the uterus, and of about its normal size. When *in situ* the organ must have been flexed laterally and twisted on its axis, so that the mass appeared to be developed mainly from its posterior wall. On making a section the tumor was found to be so firm as to be cut with difficulty, its structure was distinctly fibrous, and it was interstitial in character; at one point of its circumference, and near the fundus, there was a spot that appeared to be undergoing myxomatous change, and in the centre of the patch was a small cavity about as big as a filbert, with a cheesy or necrotic mass contained therein.

Upon microscopical examination by Dr. W. H. Porter, Curator to Presbyterian Hospital, the great mass of the tumor was found to be composed of interlacing bundles of fibrillated connective tissue, as commonly seen in fibroid tumors. This tumor, however, had a few non-striated muscular fibres interspersed, and was more vascular than ordinary fibroids. There was one very small cyst near the surface, which contained granular and fatty matter, and fibrous elements undergoing degenerative change. There was a thin layer of tissue, darker in color, surrounding the whole mass, and evidently springing from the uterus. This layer was composed principally of non-striated muscular fibres and a dense network of capillary vessels.

From the tumor containing a few muscular fibres it might be called a myo-fibroma, but the great bulk of the growth is fibrous in character.

A Course of Stenography has been organized at the Academy of Medicine, St. Petersburg, and one hundred students have intimated their intention of following it. This is the most foolish departure in the line of medical education that we have heard of yet.

A CASE OF

METASTASIS OF ACUTE ARTICULAR RHEUMATISM TO THE MENINGES—RECOVERY.

By WALTER L. RANNEY, M.D.,

LATE HOUSE PHYSICIAN TO BELLEVUE HOSPITAL, N. Y.

KATE K——, a woman forty years of age, first came under my care on the afternoon of July 14, 1880. She was then comatose, but her previous history as given by her sister, and also subsequently by herself, was as follows:

She had always been a perfectly healthy, hard-working woman, and was, by occupation, a laundress; had never been addicted to the excessive use of alcohol, but occasionally would take a glass of beer after working.

On July 7th she was washing all day, standing during this time in rather a damp place, but, with the exception of being rather tired, went to bed feeling well. The following morning she complained of pains in her joints, and by the next day was laid up in bed with what would seem to be, from her description, a typical case of acute articular rheumatism, affecting the knee-, ankle-, and elbow-joints. The pain was very severe, preventing her from moving in bed or helping herself in any way; but there seems to have been but little constitutional disturbance.

On the morning of July 13th, five days from the commencement of the disease, she found that the pain had entirely left her joints, and from being red and swollen, they had again resumed their natural contour. Thinking she was well she wished to get up, but being troubled with a headache (for the first time in her sickness), remained in bed. This headache constantly increased, and by the afternoon she suffered intensely from intolerance of light and sound, and lay tossing and turning on the bed, unable to procure relief. In the evening delirium set in, which was moderate at first, but rapidly increased until forcible restraint was needed to quiet her. This lasted till early in the morning, when she became quiet and gradually sank into a state of coma, in which condition I first saw her. She was then completely comatose, all efforts being unavailing to arouse her. The surface of the body was moist, the face rather pale, and there was no rigidity of the neck or extremities. The pupils were regular, neither dilated nor contracted, and responded sluggishly to a strong light. Her temperature was 104½ by vagina; pulse, 100, very hard, somewhat irregular, but not intermittent, and her respirations twenty a minute. There was retention of urine, which was drawn by the catheter and found to be highly acid, with a specific gravity of 1019, and containing no albumen. A careful search for cardiac or pulmonary trouble gave negative results.

Three leeches were immediately applied to each mastoid process, and an ice-cap to the head. A drop of croton-oil was dropped on the tongue, and the patient was placed on a fever-cot, tepid-water baths being given every half-hour. The temperature was taken by the vagina ten minutes after each bath, and fell gradually to 101° F. in about three hours, being kept at this point by occasional baths if it showed a tendency to rise.

July 15th.—Patient is conscious, but stupid. The temperature remains at about 100½° F., requiring but very few baths to prevent its rising. She has taken some nourishment in the form of milk, and passes her urine voluntarily.

July 16th.—Patient to-day talks sensibly. She has no recollection of anything which has transpired since the afternoon of July 13th. The *rheumatism has reappeared* in her right elbow and wrist, the joints being swollen, hot, and tender. She was taken off from the fever-cot, and the ice-bag was also dispensed with. A thorough daily examination has failed to discover any complication in the heart or lungs. The treatment now is salicylate of soda, gr. xxv. in glycerine and water, every three hours.

July 19th.—The rheumatism still lingers in the elbow and wrist, but aside from that the patient feels well. Salicylate of soda is still continued.

July 23d.—The inflammation in the joints has almost subsided; there has been no reappearance of the cerebral symptoms.

July 28th.—Patient to-day says she feels perfectly well and is going to return to work. She was again examined, and the heart-sounds found perfectly normal and the lungs clear.

It is rather a rare occurrence to have marked cerebral symptoms in simple acute rheumatism; and when they do occur, they are due to one of the following causes:

First.—Some affection of the heart or, more rarely, of the lungs. Of these complications, endocarditis and pericarditis far outrank all others as regards frequency.

Second.—Hyperpyrexia; where the abrupt rise of temperature is the striking symptom, and the cerebral disturbance follows this.

Third.—Meningitis, either as a complication or as a true metastasis, similar to the change of seat of the inflammation in the joints.

As regards the occurrence of cardiac or pulmonary complication in this case, I am positive that they can be wholly excluded as a factor in the nervous symptoms, since, as I before stated, a daily examination failed to reveal anything abnormal, and there were no rational symptoms which would lead to the suspicion of some possibly unrecognized lesion. In patients who are broken down by chronic alcoholism, or are cachectic from any cause, delirium and coma are often very marked symptoms; but these are preceded by an abrupt and excessive rise of temperature, and are simply consequent upon this. Ordinarily the temperature during an attack of rheumatism is rarely above 104½° F.; but in exceptional cases, as that of Ringer's, it has reached 111° F. I myself have seen a case where there was furious delirium, the temperature being 107° F., which delirium immediately returned if the temperature was allowed to rise again. The present case, however, was a strong, healthy woman, and one who had no alcoholic history. Her highest temperature was 104½° F., which, though higher than we generally see in rheumatism, was certainly not enough to account for the grave symptoms presented. Aside from that, the complete return to consciousness did not occur till more than twenty-four hours after the reduction of the temperature, and during the remainder of the disease there was no tendency to an exacerbation of the fever.

We are led, then, it seems to me, to regard this as a true case of meningitis, more by the doctrine of exclusion than by any very positive symptoms.

Still, the history of headache, delirium, and coma, the moderate pyrexia, the sluggish pupils, the hard, somewhat irregular and but slightly accelerated pulse as compared with the temperature, all occurring during a rheumatic attack, satisfies me that we

have here perhaps the rarest complication of acute rheumatism, and one of which Niemeyer says he has seen but one instance.

That it was a true metastasis also, I think there can be no doubt. With the disappearance of the articular swelling and tenderness commenced the meningeal inflammation, which was as rapid in its development as the same process in the joint; and almost as suddenly again disappeared, the inflammatory action reappearing in the elbow and wrist.

Whether the local bloodletting and general antiphlogistic treatment really had any influence in changing the seat of the inflammation or modifying it in any way, I am in doubt. Still, from the success in this single instance I should be tempted to give it another trial if a chance should offer. I may add that, about three weeks after the woman recovered, she was again laid up with a second attack of rheumatism, but this was speedily cured by the use of salicylate of soda, and lasted only about ten days.

Progress of Medical Science.

Radical Treatment of Hydrocele by Injection of Carbolic Acid.—At a meeting of the Philadelphia Academy of Surgery, June 7, 1880, Dr. R. J. Levis stated that in 1872 he had begun to treat hydrocele by carbolic acid injections, because a more plastic grade of inflammation than that obtained by ordinary injections was required, and because incision only accomplished a cure through suppuration. His method is to withdraw the fluid by an ordinary trocar, and then introduce the long nozzle of a syringe through the trocar into the vaginal sac. By this means the carbolic acid is thrown into the cavity, and there is no danger of its being injected into the cellular tissue of the scrotum. The carbolic acid crystals are merely liquefied by slight heat, or by a few dops of glycerine. To keep the injecting fluid ready for use at all states of temperature, about ten per cent. of glycerine or water may be added to the crystals. The amount of carbolic acid which Dr. Levis injects is one-half a fluid drachm, and this is allowed to remain in the vaginal tunic. The operation is almost, if not entirely, painless, because of the local anæsthetic action of carbolic acid. The patients sometimes exclaim at the moment of introduction, but have a sensation of numbness rather than of pain. The pain, when tincture of iodine is employed, is much greater. Care should be observed to allow no acid to flow upon the external surface of the scrotum, for pain and inflammation will follow such contact. After the injection the patient is permitted to walk about the house until the weight and slight soreness of the scrotum cause him to lie upon a bed or lounge. The results of this method of treatment are excellent, for undue inflammation does not occur, there is no marked pain, and a radical cure generally ensues. Dr. Levis has never seen suppuration or sloughing follow this manner of dealing with hydrocele.—*Phila. Medical Times*, November 6, 1880.

Hip-Joint Disease—Death in Early Stage from Tubercular Meningitis.—Dr. De F. Willard contributes an article to the *Boston Medical and Surgical Journal*, November 4, 1880, with microscopic examination by Dr. E. O. Shakespeare in a case of hip-joint disease, in which death resulted at an early stage from tubercular meningitis. The patient, male, aged five years, whose mother died of phthisis, was presented at the orthopedic clinic of the University of Pennsylvania. One year ago, apart from special known injury, he experienced a slight lameness, without pain, but at night complained of a sense of weariness about the hip, and a restlessness of the limb was noticed after retiring. These symptoms were the very earliest indications of inflammation of this joint, antedating rigidity of the muscles, pain, or lameness. The lameness increased, and the discomfort gave rise subsequently to pain. A diagnosis of hip-joint disease was made after a thorough examination, and treatment ordered accordingly. Patient gained steadily in every particular, growing fat and hearty under iron and cod-liver oil. Six weeks later there was no pain or discomfort of any kind; no induration could be felt about the joint; and flexion, extension, abduction, and adduction, could be performed to a considerable extent without discomfort. In January, however, he commenced to complain of headache; vomiting suddenly set in and continued persistently for three days. The pain in the head became of the most intense and excruciating character, causing piercing shrieks from the child at each onset; obstinate constipation was present; the characteristic facies, stupor, slow pulse, convulsions, and coma of tubercular meningitis, followed in rapid succession, with death upon the sixth day after the vomiting commenced, and two months after the child was first examined. The post-mortem examination was not thorough, but possession of the head of the femur and entire acetabulum was obtained, and the following conclusions were arrived at after a microscopical examination by Dr. Shakespeare. The morbid process affected the synovial membranes. The history of the case, both clinical and pathological, would seem to support the views of those who defend the doctrine that in a certain depraved animal organism inflammatory products tend to caseous degenerations, which may ultimately cause a local or general infection of the various tissues of the animal, and a limited or extensive irruption of tubercles; while there was a slight fatty degeneration of the cartilage-cells at the surface of the cartilage, there was no such decided alteration of this kind as Cornil and Ranvier and some other authors believe to be the initial and essential lesion in so-called scrofulous hip-joint disease. The microscopical examination showed further that the disease had at no point advanced to the stage of ulceration, and also that fatty degeneration had barely commenced; still, infection of the system had resulted, thus showing that while the inflammation could not be differentiated from the simple form, yet that there lurked behind this process a systemic condition, hereditary or acquired, predisposing to inflammation of a low grade —"languid." It is not uncommon to find cases both of hip- and spine-disease dying of tubercular meningitis, but such a result would not occur at an early stage of the disease were the previous condition of the child untainted.

Fracture of the Rim of the Acetabulum.—An article by Dr. Senn, of Milwaukee, entitled "A Contribution to a Knowledge of Fracture of the Rim of the Acetabulum, based on the Reports of Twenty-seven Cases and Experiments on the Cadaver," is an exhaustive and comprehensive document, and merits the attention of surgeons generally. Seven experiments were made on the cadaver which demonstrate how difficult it is to fracture the rim of the acetabulum, and tend to corroborate the views of the ma-

jority of surgeons, who consider this injury one of the rarest accidents in surgery. These experiments also lead to the conclusion that fractures through the floor of the acetabulum are of more frequent occurrence than simple fracture of the rim, and are the result of a less degree of violence. Of the twenty-seven cases, eighteen were males, four females, and in the remaining five the sex is not stated. The disproportion between the males and females is explained by the fact that the former are more frequently exposed to severe accidents. The extremes of the ages were eighteen and seventy eight years, so that most of these cases occurred during the time of life when most exposed to grave injuries. The symptoms presented are those of dislocation and fracture combined; the symptoms of the former resemble ordinary dislocation, while the latter are directly referable to the broken bone itself. A certain degree of displacement of the head of the femur was present in all cases where a diagnosis was made during life. In a large majority of cases that portion of the rim is fractured which is in the direction of the usual form of dislocation, so that the same injury which produces a dislocation may also cause a fracture, provided it is sufficient in intensity and the limb *abducted* at the time the injury is received. Inversion of the foot and rotation of the femur inward were present in fourteen cases, while the opposite condition existed in three cases, and in ten cases no mention is made of this symptom. The characteristic symptoms of the injury are those which are referable to the fracture itself, and these are crepitus, easy reduction, and difficult retention. The crepitus differs from that of ordinary fractures: it is the roughness obtained from rubbing an articular surface against a broken surface of bone and is not as loud or distinct. Crepitus and a tendency to reluxation are the symptoms on which we place the most reliance to differentiate this fracture from simple dislocation. In some cases Middledorff's method may be of great service to determine the existence of fracture of the rim. After reduction of the limb has been accomplished, a long, stout needle is passed through the tissue to the supposed seat of the fracture. By lateral movements of its point the defect in the margin, as well as the roughness of its surface, is ascertained. An effort should now be made to fix the detached fragment with the point of the needle, and rubbing it over the broken margin a rough crepitus is elicited. Regarding the prognosis, Dr. Senn is of the opinion that all uncomplicated fractures of these bones tend to recovery. In twenty-three cases where the result is noted in this regard, thirteen recovered and ten died. The prognosis is less favorable if the floor of the acetabulum is also implicated in the fracture. Of four cases of this sort only one recovered. The best method to prevent reluxation is to make the unbroken portion of the rim a support for the head of the femur and to secure immobility to the hip-joint, by applying a permanent dressing, including the pelvis and both lower extremities. When the depth of the rim is not sufficient to prevent reluxation by muscular contraction, permanent extension and fixation are necessary for the maintenance of the bone *in situ*.

Pilo-Nidal Sinus.—Dr. R. M. Hodges read a paper before the Boston Society for Medical Improvement, November 8, 1880, entitled "Pilo-Nidal Sinus," which is described as a deep, symmetrical, and somewhat conical dimple, occasionally existing near the tip of the coccyx, well forward toward the anus, in the cleft between the nates. Sound and natural as regards integument, resembling to a certain extent the navel, with the dimensions of which it may be compared, it is fixed at its deepest portion, and the depression cannot be obliterated or made shallower by stretching the skin. Congenital in origin, it attracts the attention of nurses or mothers, and in infancy inquiry is made as to its significance. Later in life, opportunities for inspection being less frequent, it passes unobserved. It probably represents an imperfect union of the lateral halves of the body, involving the integument only. Dr. J. Mason Warren, in 1867, recorded eight or ten cases. It is generally stated to have existed for a long period, and is supposed to be a fistula in ano, an impression which, if at first shared by the surgeon, is quickly corrected by the introduction of a probe, which passes a considerable depth above and below the opening, indicating a cavity of an inch or more in diameter; but it does not enter the gut. On exposing the interior by an incision a certain quantity of pus is evacuated and a lock of loose hair is found occupying the space. The cavity containing the hairs, which are always short and without bulbs, has no cyst or lining membrane, or other characteristic suggestive of a congenital dermoid wen—merely the granulating walls of an ordinary suppurating sinus, with no trace or suspicion of hairs growing from its surface, or of isolated spots of cuticle from which they might have been shed. The lock of hair being removed, the sinus fills up with new tissue and in due time heals by a solid cicatrix. For the development of this rather singular lesion, to which, for the sake of designation, the name of pilo-nidal (*pilus*, a hair, *nidus*, a nest) sinus is given, the following elements are necessary: 1st, the presence of a congenital coccygeal dimple; 2d, abundant development of hair—hence adult age, and almost of necessity the male sex; 3d, insufficient attention to cleanliness: consequently its subjects, as a rule, must be persons of the lower class, and the affection, one met with in hospital or dispensary rather than private practice.—*Boston Medical and Surgical Journal*, November 18, 1880.

A New Physical Sign in Thoracic Aneurism.—Dr. Drummond, of Newcastle-on-Tyne, has demonstrated before the Northumberland and Durham Medical Society a physical sign which will apparently be of considerable value in the diagnosis of aortic aneurism, should it not turn out to be pathognomonic. When a patient who is suffering from thoracic aneurism inspires deeply, and then closes the mouth and expires slowly through the nostrils, a puffing sound is heard on auscultating the trachea, which is synchronous with the cardiac systole. This sound is best heard with the biaural stethoscope, and is evidently a sudden involuntary expiration caused by the sudden systolic expansion of the sac expelling air from the chest. This physical sign has been demonstrated by Dr. Drummond to be absent in cases of aortic valvular disease without aneurism, while it is present in every case of aneurism which has come under his notice since the discovery of the sign, viz., four; and he also thinks it will be of importance in distinguishing between aneurism and sarcoma of the lung.—*Dublin Journal of Medical Science*, November, 1880.

The London Hospital Sunday Fund.—The council having charge of this fund has decided not to make grants to hospitals in which religious liberty is not allowed, or in which the religious principles of the patients are tampered with.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 1, 1881.

THE ETHICS OF CONSULTATIONS.

An honorable man needs no code to govern him in his relations to his fellows, but for one who is not actuated by the right principles, there is no set of rules which cannot be violated by him to suit his purpose. So many are the ways, for instance, by which the artful man can take advantage of his position as consultant that there appears to be a growing distrust in the real utility of consultations. We have heard some startling news bearing upon the point from a neighboring town. There it is openly acknowledged to be quite unsafe for any obscure practitioner, who cares to keep his patients, to call in as counsel one who is older or has more reputation than himself. We are glad to know that this state of things does not exist to any great extent in this city, but exceptions to the rule of honorable dealing are sufficiently numerous here and elsewhere to warrant a reference.

It is generally understood that, when a physician is called on by another as a consultant, the former must not attend the case thereafter as a family physician. The simple reason for this appears to be that the consultant would not have been known to the patient except through the attending physician, and that, consequently, he must not take advantage of such endorsement, directly or indirectly, to serve his private ends. Such an understanding protects the attending physician, at the same time gives to the patient competent and trustworthy counsel in time of need. If this were not so the attendant might be tempted to discourage consultations, and thus deny himself much valuable aid.

Although it may appear absurd to deny the right to a patient of employing the consulting physician if he so desires, this disadvantage is more than offset by the great benefit of consultations, properly conducted and properly encouraged. If the patient himself calls in a physician to consult with his attending medical adviser, the consultant is under no obligations to the latter regarding future non-interference with the patient. The consultant, under the circumstances, is not debarred from taking the case, if the patient chooses, at any future time, to discharge his medical attendant. A sense of ordinary justice, however, will compel him to do all he can to sustain and endorse the previous attending physician.

With the cultivation of the different specialties some of the ordinary amenities which obtain between attending and consultant are either in the hurry of business, or from pure thoughtlessness, or perhaps from less excusable reasons, apt to be lost sight of. Some specialists assume entire and permanent charge of a patient even when sent to them for temporary advice by the family physician. It is hardly fair to assume either that the latter cannot be trusted to carry out directions, or that the specialist has a natural right to every case in his line of practice. The only reason for taking absolute charge of the patient is the direct request to do so by the family attendant. The attending physician, as the trusted adviser of his patient, takes all the responsibility of continuing to treat the patient, if he so desires. But some specialists so much exceed their ordinary privileges in this respect that there is much complaint from general practitioners. Some of the latter have informed us that they do not care to run the risk of losing control of their cases by sending them to certain specialists. For not only has it happened that the specialist will keep the patient sent to him, but when any new disease develops itself will send him to a friend in another specialty, and not unfrequently, even for the treatment of general diseases, take the liberty of recommending another than the physician who originally sent the patient to him. Such a practice is an outgrowth of the system of helping different members of a clique, be they connected with a college, a society, hospital, dispensary, or office. Not that these gentlemen believe it is impossible to find any available talent outside of their own little circle of professional friends, but that they are bound by a community of interests not to recognize it. Such a feeling is sometimes carried to the extent which is far from prudent when the real interests of the patient are considered. Of course no prudent practitioner risks such an experiment very often, and takes occasion to give the right sort of advice to his professional friends. We are happy to say that such cases are exceptions to the genera lrule among specialists as, after completing treatment, they refer the patient back to the family physician. It is not expected that such a rule holds good with a patient who, while not under actual treatment by his family physician, calls of his own accord to consult a specialist. We are constrained to make the foregoing remarks in consequence of several cases in point which have been recently brought to our notice.

RENAL ALBUMINURIA AS A SYMPTOM.

PERHAPS there is no one question relating to pathology which is at present attracting more universal attention than the nosological significance of renal albuminuria. It is a subject which has induced recent elaborate experimentation, that in its turn has led to numerous important contributions to current medical literature. Once more it has become a prominent object of discussion by professional societies. And it even looms up in the mind of the practitioner as a practical question involving or determining therapeutic action.

It is easy to understand why this should be so. The importance which the physician attaches to this symptom, and the views he entertains concerning its origin and meaning, directly affect the conduct of his treatment in a given case. Moreover, the presence in the urine of this abnormal ingredient (for such it must be considered despite the contrary statements of some authors) is readily detected, and often as readily interpreted as a palpable manifestation of existing disease. Any obscure case, which at first sight may have appeared hopelessly intricate to the puzzled diagnostician, with the detection in the urine of an albuminoid substance suddenly, as if by charm, loses its questionable character and ceases to bewilder. Albuminuria did it. Albuminuria is responsible. But, if the routine practitioner is thus easily satisfied, the rational physician and man of science is not. Here as elsewhere the latter strives to ascertain the why and the wherefore. And it is the results of inquiry in this spirit which have modified, and are still modifying, our views respecting the significance of albuminuria.

For a long time the primitive simplicity of Bright's views swayed the professional mind, and, according to the then dominant ideas, albuminuria meant renal disease. Even at the present day, by some, the two terms are believed to denote one and the same thing. When, however, the rapid advances of pathological histology revealed some of the complexities of the subject, other factors came prominently to the front. Soon sharply defined distinctions were created separating diffuse from parenchymatous, and both from renal cirrhosis. Albuminuria was now only one in a train of symptoms indicative of kidney disease. To-day the pathogeny of albuminuria, although by no means in a completely satisfactory condition, is still better understood. We know now that various affections are associated with the appearance of albumen in the urine. Thus, Dr. Ellis has contributed much valuable information on this topic by compiling a table of the manifold conditions under which it occurs, and the list, though avowedly incomplete, furnishes 150 such conditions—and all exclusive of renal disease. Of course one should not look upon attendant phenomena in the light of causes, unless there is some satisfactory reason for so connecting them. Though the number of etiological factors is large, we have no ground for presuming that it reaches the figures just indicated, nor do we believe that Dr. E. wishes it so understood.

Transient albuminuria may be observed in a great variety of disturbances, and even the prolonged presence of albumen in the kidney secretion does not *per se* argue permanent histological change in those organs. Protracted muscular exertion may lead to albuminuria. Certain articles of diet, notably eggs, produce it—a change in the condition of life may lead to it. The effects of climate may also act as exciting causes. And all this in persons of apparently excellent health. On the other hand, slight ailments may be found in connection with albuminuria, and *vice versa*. Indigestion appears to be frequently accompanied with the renal excretion of albumen. Stimulation of the spinal cord below the medulla, irritation of the renal nerves, and other neurotic influences, give rise to it. Fürbringer (*Zeitschr. für klin. Med.*, vol. i., sec. 2) records, among other cases, the interesting instance of an otherwise healthy physician subject to albuminuria, in whom nervous depression was always followed by an increase in the amount of albumen voided.

Da Costa and Longstreth, as the result of recent important investigations (*Am. Jour. Med. Sc.*, July, 1880), even claim that "in Bright's disease, especially in the contracting kidney, there exists a constant lesion of the renal plexus." Moreover, that this is the true cause of the renal malady.

The albuminuria of fevers may also be the result of vaso-motor disturbances. In anæmic persons albumen may appear in the urine (Edlefsen, *Mit. d. Ver. Schles.-Holst. Aerzte*, 1879, No. 2), especially after exertion. Cardiac failure, or at any rate a relative weakening of the heart's power, has been pointed out as the probable cause of the symptom in such persons. This appears to be a plausible explanation enough in the light of recent investigations by Runeberg (*Deut. Arch. f. klin. Med.*, vol. xxiii., p. 41, and vol. xxiv., p. 248), for the permeability of animal membranes becomes greater under low than high pressure. Thus, Runeberg explains the transient albuminuria of healthy persons in the following way: he asserts that the transudation of serum-albumen takes place in the glomeruli on account of the increased permeability of the walls of the blood-vessels composing the tufts. The epitholial investment of the latter participate in this abnormal permeability. As the cause of this augmented permeability there may act any factor resulting in the diminution of the difference between the blood-pressure inside the glomeruli and the external counter-pressure of the renal tubules. In this connection it is well to note that Dr. Munn, of this city (MEDICAL RECORD, March 29, 1879), reported that among a number of appli-

cants for life insurance, he found albuminuria in eleven per cent., where the individuals appeared, after careful examination, to be otherwise in perfect health.

Persistent albuminuria is also explained by Runeberg as the result of structural alterations of the vascular tufts. It seems that Leube (*Virch. Arch.*, vol. lxxii., p. 145) and others have taken exception to the unavoidably theoretical deductions of Runeberg, but they certainly appear to deserve attentive consideration.

Taken altogether, it must be confessed that there exists just now a rather unsettled state of professional opinion on this important subject. Certainly, we lack the desirable basis of assured knowledge, and though some new points of interest have been elicited, the physiological laws governing the passage of albumen into the urine are still in part unknown. The practical importance of a complete comprehension of these matters should prompt untiring efforts and new researches in this direction. Meanwhile we should solace ourselves with the comforting thought that albumen may often be made to disappear by proper attention to the exciting cause, which may frequently be found if diligently sought for. Albumen, though occasionally an ingredient in the urine of healthy individuals, indicates an abnormal state at the time it is voided, and no rational physician can be otherwise than extremely watchful whenever it makes its appearance.

THE GROWTH OF THE CITY AND THE RELIEF OF ITS POOR.

The Society for Improving the Condition of the Poor is an organization which has done more than any other to carry out intelligently the objects indicated by its name. Its annual report for 1880 contains evidence of much work done and of a careful study of the needs of the poor of the city. In regard to the condition of our tenement-houses, and concerning the abuses of medical charities, there are some especially interesting statements.

The year 1879–80 witnessed a remarkable increase in the city's prosperity. The effect of this is shown in the increased number of houses built and in the greatly diminished number of applicants for relief at the offices of the society. There were nearly seven hundred new tenement-houses constructed in this city in 1879, and probably a larger number during the present year. Twenty-four millions of dollars were spent upon buildings during 1879. Such activity could not fail to furnish employment to many, and the society report that the applications for relief, which in 1878–79 were about ten thousand, in 1879–80 were only about six thousand.

In discussing the sanitary condition of our tenement-houses the report does not speak very encouragingly. The increase in the number of these houses has not appreciably affected the density of the population. The elevated roads have not carried the working population up town. On the contrary, workingmen seem to prefer a gregarious life in Mulberry street to a healthful, but more isolated one in Harlem. The morning and evening trains on the east side are loaded with workingmen who go uptown to their employment and return in the evening to the smells of a down-town tenement. The census returns for 1880 show that the population of wards lying south of Fourteenth street remains nearly the same as in 1870. One ward, however, has gained about 10,000, while the whole district, without losing in population, has undoubtedly a less number of dwellings than it had ten years ago, and is, therefore, practically in a more crowded state.

The sanitary condition of the tenement-houses has, however, improved somewhat; although, according to the present report, is it still very bad. The society's inspector states that "the condition of the tenement-houses as described sixteen years ago is their condition to-day." The agent, in the months from February to June, 1880, made 813 inspections; he found 693 defective houses. Of these, 237 houses were reported to the Board of Health, which body remedied defects in 87 cases, partly remedied them in 59 cases, and did nothing in 91 cases.

For the future, it seems likely that the most which can be done for a long time at least, will be to teach and enforce sanitary methods in the tenements now existing, and to see that new tenements are built with as few defects as possible. The so-called model tenements do not appear to be a success, so far as reaching the lowest and poorest classes is concerned. They are generally occupied by clerks, small tradesmen, and persons a little above the class of day-laborers.

The report touches more briefly than we could wish upon the subject of the abuses of medical charity. It commends the new rule adopted in several of the city dispensaries of charging a small fee for medical advice, a rule which we think should be praised with great reserve. The report continues: "It has long been feared that the habit of dependence and willingness to take alms has been implanted or cultivated by dispensary attendance. The good nature of physicians has also been thus abused by many who could well afford to pay for advice, and the community has been needlessly taxed for individual benefit." A brief history of the present movement instigated by the British Medical Association and prominent medical men and laymen, to organize a confederation of provident dispensaries in the city of London is given.

It is very much to be desired that the Society for Improving the Condition of the Poor should take up this subject of the abuse of medical charities with more seriousness than it has yet done. There is no

one direction in which charity is more pitifully misused, or in which the spirit of pauperism is more diligently fostered. The society could do more probably, than any other lay society to help solve the question. How our dispensaries and hospitals should be managed as regards the receiving and treatment of non-paying patients is a question fully deserving the attention of an organization which aims to treat pauperism in all forms in a rational manner. We would call the attention of its officers to this point, therefore, as one that deserves consideration in their future labors.

THE AMERICAN MEDICAL COLLEGE ASSOCIATION.

THE *Chicago Medical Journal and Examiner* has been devoting a large share of its editorial space to the subject of the American Medical College Association, and it has chosen to take us to task for certain editorial comments upon that body made some time ago. We are accused, it seems, of speaking ill of the College Association, and of "a Pecksniffian assumption that there is nothing of value in the medical institutions of the country" outside of the East. Our particular errors are that we attributed the withdrawal of certain eastern medical colleges from the association to the fact that they thought such an association could no longer benefit them. Also, we are accused, with much iteration, of having spoken of the western and southern medical colleges as "medical colleges scattered throughout the West and South."

The *Chicago Medical Journal and Examiner* has misapprehended the spirit in which the article it criticises was written. We are, and have been, entirely friendly to the American Medical College Association. It has accomplished much good, and, we hope, will do more. We stated, however, that it could never adopt for all its members the highest educational requirements desirable without a fatal loss of membership. This is absolutely true, and nothing has been brought forward by the *Journal* to disprove it. The strain of such small reforms as that of raising the fees to $75 has cut down the Louisville schools one-half, while the Nashville schools, though members of the Association, have made no increase in fees at all. The much-praised four-year medical school at St. Paul is said to be with few or no pupils.

There is no doubt of the fact that a large number of medical colleges have not the means of acceding to high educational requirements. There are two such colleges in the East, but there are fifty-three colleges in the West and South. Hence the natural emphasis which we put upon the institutions in that part of the country.

The facts in regard to the distribution of medical colleges and students are as follows:

Total number of medical colleges in the United States*	69
Number in New England and Middle States	16
Number in West and South	53
Total number of students	8,279
Average for each New England and Middle State college	216
Average in West and South	90
Total students in New England and Middle States	3,467
Total students in West and South	4,812

As near as can be learned from statistics given by the United States Commissioner of Education, there are nineteen western and southern colleges that have not over fifty students, and two of these have no students at all. This number of medical colleges, nineteen, is considered enough to supply all of Great Britain. The idea, therefore, that there are a good many small medical colleges throughout the West and South, if incorrect, is a very natural one. That these colleges have so many students as they do, may be explained to some extent by the fact, that up to the present year nearly one-half of them charged from $10 to $50 per year for tuition.†

But we wish to assure the *Journal and Examiner* that we intended no partisan plea for eastern medical colleges. The causes assigned for the withdrawal of the two New York colleges from the Association were correctly given, as we believe. But we are not the "organ" of any institution, and have not the slightest desire to imitate our able contemporary in making use of the discussion to advertise local schools. Our interests are those of the profession. We would like to see medical education advanced everywhere, because it would benefit the general practitioner. If the western schools have done more than the eastern to raise educational standards, as our contemporary argues, we will cheerfully admit the fact. There does not seem to be any special need for the *Journal* to continue, as it promises, its animadversions upon us; but "error is ever talkative."

HELP FOR STAMMERERS.

A CONTRIBUTOR to *Chambers' Journal*, who, according to his own assertion was a most habitual, unmistakable, and inveterate stammerer, gives his theory with regard to the production of what might be termed this vocal deformity, and details the method by which he effected a cure.

After having his life "thoroughly embittered by this malady" for about thirty years, he met with an article on the subject by Dr. Arnott, in which it was suggested that since consonants are the stammerer's deadly enemies, the prefixing of the sound of *e*, as in

* Report of United States Commissioner of Education, October, 1880.
† Ibid., 1878.

the French words *de, le, me, se,* to all words beginning with a consonant, would prove an unfailing remedy. This plan was tried with some benefit, but something more was required for words with consonant initials in the middle of a sentence, as well as for syllables with consonant initials in the middle of a word. As to *w, y,* and *u* as initials, they seemed to present insurmountable difficulties.

After considering the subject still further, he decided that, as consonants at the beginning of a word are so very troublesome, if a method could be devised for bringing them to the end of a division instead of the commencement, a great object would be attained. Once the glottis being opened by a vowel-sound, the consonant would follow. The aim of the stammerer is to prevent the glottis from closing when once it is opened.

As a further step in the development of this plan, sentences were written out in the ordinary way, and then rewritten, so that the initial consonant became the final letter of the preceding word. The sentences thus constructed were then read over and over, until in a few weeks the improvement was extraordinary.

Before entering upon a trial of the method which proved so satisfactory in the case under consideration, it must be understood that the stammerer should speak slowly and with affected ease, allowing the words to *flow* out rather than to deliver them with a jerk. Besides, when it is recommended to prefix the French sound of *e,* as in *le, de, me, se,* it is not intended that this sound should be conspicuous, but used rather as a glottis-opener, making way for the advancing consonant. Further, the statement which is sometimes made, that no stammerer ever experiences any difficulty in the enunciation of vowel-sounds, is not true, for *w, u,* and *y* are, as initials, often decided *pièces de résistance.*

Now to illustrate the proposed plan. In the enunciation of such words as have consonant or compound consonant initials, like *br, pr, dr, st, sl,* the prefix of *e* will be an amply sufficient aid. Under this head would come such sentences as, "*My* friend who has just spoken;" "*But* there is a fatality;" "*Now* all that has to be changed;" "*That* showed the power;" *N*umbers, *D*euteronomy, *S*cotland, *S*pain. Some of these words would often prove very embarrassing to a stammerer without extra help.

In case one or more words beginning with consonants occupied the body of a sentence, the sentence should be so constructed as to make the initial consonants come at the end of a division. The sentence, "May he rest in peace," would then become "Im-ay heer-est inp-eace," and this should be read aloud many times, studying to make it sound like the original. Such a division is not necessary for every sentence, but only where an obstacle presents, and this can usually be anticipated. Besides, when one formidable word has yielded, a host of others will follow suit. The well-known sentence, "I came, I saw, I conquered," becomes "Ic-ame, Is-aw, Ic-onquered.'

Where *w* stands as initial, the sound of *oo* as in moon should be used; for *y,* the sound of *ee* is called in; and for *u,* the sound of *ee* followed by the sound of *oo.* Certain words, such as universe=eeooniverse, unanimons=eeoonanimous, usual=eeoosual, should be written out and repeated aloud as before. The substitution of the equivalent sounds for *w, y,* and *u* is said to afford a relief almost incredible, but care must be taken not to *dwell* on these substitutions, but pronounce them nearly as one syllable. Practice is of course always necessary.

In conclusion, the writer adds that the benefit of this system has not been confined to himself alone, and Canon Kingsley, in gratefully acknowledging these hints on the cure of stammering, said: "For the torments I have suffered since I was six years old, God alone knows, or will know; still to me every stammerer is a friend at once by unity of sorrow—after all, perhaps the most sacred unity on earth."

Reviews and Notices of Books.

Cutaneous and Venereal Memoranda. By Henry G. Piffard, A.M., M.D., and Geo. Henry Fox, A.M., M.D. Second edition. 16mo, pp. 310. New York: Wm. Wood & Co. 1880.

Ophthalmic and Otic Memoranda. By D. B. St. John Roosa, M.D., and Edward S. Ely, M.D. Revised edition. 16mo, pp. 298. New York: Wm. Wood & Co. 1880.

It is evident that these books have supplied a want in the medical community, from the fact that a second edition has been called for so soon after the first had been issued. While by no means intended to be exhaustive treatises, they furnish, in crisp, terse, and easily accessible form, the leading facts of pathology, symptomatology, and treatment of the diseases and affections of which they treat. It is much easier to be diffuse than to be brief, and much simpler to expand than to condense; and it is therefore no small praise when we say that the authors have brought within this small compass all the most important facts, so far as known down to the present time.

The Student's Dose-Book and Anatomist. By C. Henri Leonard. Pp. 150. Detroit: Leonard's Illustrated Medical Journal. 1880.

We greatly question the usefulness or even harmlessness of such little books as this, which profess to give anatomy, materia medica, therapeutics, and obstetrics, as well as numerous facts of chemistry, toxicology, and practice of medicine, within the space of a few pages. If they are intended to take the place of larger and more complete works, they must inevitably lead to superficiality of knowledge; and if they are not supposed to be complete, they are superfluous. All that they are good for is "cramming" for examination. The book in question is about as poor a specimen of its class as we have met with, and it seems to have been gotten up as much to advertise

a certain drug-house as for any other purpose. It is not even properly bound, as in the second part pages 30 to 47 are missing, and instead, pages 65 to 80 of the first part are bound in.

THE COMPEND OF ANATOMY. By JOHN B. ROBERTS, A.M., M.D. 24mo, pp. 191. Philadelphia: C. C. Roberts & Co. 1881.

As the author says in the preface, this is not intended to take the place of more elaborate works on the subject, but as an aid to the student in the dissecting-room and in following a course of anatomical lectures. As far as possible, everything is arranged in tabular form, so that all the essential points may be seen at a glance. Thus, one table gives the name, origin, insertion, action, and innervation of the muscles; another gives the names of the openings of the skull, and tells what passes through them, etc. It is printed in clear type, on tinted paper, is well bound, and will not only be found useful by the student, but will be of service to the practitioner in enabling him to review, in a short time, matters which are apt to escape the memory with the lapse of time.

TRANSACTIONS OF THE MINNESOTA STATE MEDICAL SOCIETY, 1880. 8vo, pp. 190. St. Paul: H. M. Smyth & Co.

THIS embodies in official form the proceedings of the last session of the Minnesota State Medical Society, an account of which appeared in the RECORD at the time. After the usual addresses of welcome, the reports of the special committees and sections were read. It may surprise some of our readers to be informed that the committee on surgery believed that "more is claimed for the Lister treatment than it really deserves." In support of this statement, the chairman cites the results of Lister's own operations, "of which he has no reason to be proud." Bigelow's operation is lauded "among the advances in surgery in the past year" (?), and the reintroduction of hot water as a styptic is called to the attention of the members.

The report of the Section on Practical Medicine includes a paper on the treatment of empyema, by Dr. Talbot Jones, with the report of a case in which the author operated, inserting a drainage-tube, and the patient recovered in six weeks. Dr. Flagg contributed a paper on diphtheria, from which he concludes that throat diseases of various forms are prevalent during epidemics of diphtheria.

The Committee on Gynecology seem to differ from that on surgery as to the usefulness of the antiseptic method—at any rate, in gynecological operations. They also contribute papers on hystero-epilepsy, death from the expulsion of a musculo-fibroid tumor of the uterus, and post-partum hemorrhage; in the latter condition the use of the faradic current is especially lauded. In the Section on the Nervous System there were papers on cirrhosis of the liver with singular nervous manifestations, on locomotor ataxia, and on white cerebral softening. One of the most interesting papers is on medical jurisprudence, giving the history of a patient with organic heart-disease who was attacked and beaten by two men. On his death, five months later, his assailants were tried for manslaughter. There was a great mass of medical testimony taken as to the probable effect of such a sudden beating on the life of a man with cardiac disease. But the prosecution did not make out a case, as the prisoners were dismissed on the ground of insufficient evidence.

The Section on Ophthalmology made reports on color-blindness, senile cataract, tobacco amblyopia, and accidents to the eye. The Committee on Medical Education endeavored to impress upon the members the necessity and expediency of adopting the metric system. The miscellaneous proceedings include an able essay on heredity, by D. Daniel Leasure; one on diseases of the tonsils, by Dr. D. W. Hand, and three surgical cases by Dr. Talbot Jones. A simple method of compression of arteries is suggested by Dr. Palmer, without constriction of the rest of the limb. This consists of: a band of plaster-of-Paris around the limb, and a fenestra, through which a compress is placed upon the artery, and tightened and held in place by an elastic roller. The article on nasal catarrh, by Dr. Jay Owens, will be interesting in connection with the recent discussion before the Academy here; the author believes in its constitutional as well as its local origin, and treats it accordingly. We are somewhat surprised to be informed that in New York city . . . . a majority of the adult population are afflicted with this disease. A case of cardiac hypertrophy is related, in which fluid in the pericardium was diagnosed and aspirated for. Amputation at the knee-joint, without the use of the saw, is regarded as preferable to the usual operation. The proceedings close with a tribute to the late surgeon, William J. Sloan, Medical Director of the Department of Dakota.

ATLAS OF SKIN DISEASES. By LOUIS A. DUHRING, M.D. Parts V., VI., VII. Philadelphia: J. B. Lippincott & Co. 1879–80.

WE have, in a previous notice, said something regarding the very superior character of this atlas. Succeeding numbers have abundantly fulfilled the promise of excellence first given. The plates are chromo-lithographs and executed in the very best style of the art, forming probably as good substitutes for actual living cases as can be furnished.

The plan of the accompanying text is continued on in the same way as at first. A clinical history of the patient whose diseased skin is lithographed is given in full. Further points in regard to the symptoms, pathology, differential diagnosis and treatment are then given. The language of the text is clear, concise, and to the point, and is sufficient. It would of itself make a very good clinical work on skin diseases.

In Part V., scabies, herpes zoster, tinea sycosis, and eczema (vesiculosum) are illustrated and described. The accompanying suggestions for treatment are here as elsewhere very practical and valuable. The case of scabies was treated with sulphur ointment, ʒ j. to ℥ j. The patient was also directed to use warm alkaline baths, to apply the ointment twice daily, and to keep up the treatment for four days. In this way he was soon cured. The cases of herpes zoster and of tinea sycosis are treated by the usual methods. They are both beautifully typical ones. Indeed, the author seems to have been fortunate in getting thoroughly "classical" cases for all the diseases described.

Part VI. contains syphiloderma (pustulosum), erythema nodosum, seborrhœa, and eczema (papulosum). The case of seborrhœa is a remarkably good one, and illustrates both the dry and oily variety of the disease. The treatment advised for this was mainly local. It consisted in directing the crusts to be removed and the parts thoroughly cleansed with potash soap. Sulphur ointment was then applied. Tar ointment, carbolic acid, and oil

of cade are also recommended, and in obstinate cases internal remedies are added, *e.g.*, the sulphides with cod-liver oil.

Part VII. treats of eczema (pustulosum), impetigo contagiosa, syphiloderma (papulosum), and lupus vulgaris. The first two plates are of the usual high merit. The last one appears too diagrammatic to be perfectly satisfactory.

On the whole the high standard of this atlas is kept up throughout these later numbers, and it is safe to say that the work forms one of the best practical contributions to dermatology that this country has made.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 8, 1880.

Dr. T. E. Satterthwaite, President, in the Chair.

STRANGULATED HERNIA.

Dr. J. W. Howe presented a specimen of strangulated hernia with the following history: L. M——, a tailor, aged fifty-one years, was admitted to St. Francis' Hospital October 15th, suffering from a strangulated oblique inguinal hernia. Twelve months previous to admission, while lifting a heavy tailor's iron, a tumor made its appearance in the left inguinal region and scrotum. The contents of the tumor were replaced by the patient without difficulty, and there were no further symptoms of hernia until the day before his admission to the hospital, when, from the same cause as before, the tumor reappeared. This time the tumor was painful, and could not be reduced by the patient.

A physician was summoned who applied warm water and chamomile leaves, followed by taxis, but without avail. At the end of twenty-four hours the physician applied a truss and sent the patient to the hospital, unrelieved of strangulation.

On admission the patient complained of great pain over the tumor, particularly when the latter was pressed upon. He had had no passage from his bowels since the previous morning, nor had his bladder been emptied during that period. The abdominal cavity was distended, and gave a dull percussion sound below, and contained fluid. The pulse was small, irregular, and frequent. All the symptoms were much more grave than were usually witnessed in a strangulated hernia of twenty-four hours' duration. He had no stercoraceous vomiting; indeed, the patient seemed too weak to vomit. After etherization the sac was opened in the usual manner. A large mass of coagulated blood was found covering the intestine, the results of the taxis and ignorant application of the truss. The structure was tight, and when cut a large quantity of serum—over a gallon—escaped from the abdominal cavity. The intestine was much bruised at one point, but in other respects was not injured. It was returned to the abdominal cavity, and the usual dressing applied. Death took place twenty-four hours after the operation.

The autopsy was made by Dr. Wendt, curator to the hospital. The cavity of the abdomen contained a large amount of brownish colored fluid. The intestines were congested, and were loosely matted together by pseudo-membrane. A piece of intestine, six inches long, and more congested than the rest, was covered with purulent false membrane. An oblique line of ecchymosis was found in the serous coat of this part extending about two inches into the mesentery, also large and small ecchymosis on its mesenteric attachment. The visceral and parietal peritoneum were mottled. There were no signs of peritonitis about the cut or the internal ring. Both kidneys were congested, and the spleen was in the condition of perisplenitis. The liver was in the atrophic stage of cirrhosis.

The specimen was presented not so much on account of its pathological as its clinical interest, as it illustrated a method of treatment which was not uncommon among ignorant practitioners.

Dr. Carpenter thought that the clinical features of unusual interest in the case were the sudden occurrence of a hernia, which filled the scrotum, and its easy reduction by the patient.

THE BAD EFFECTS OF UNSKILFUL TAXIS.

Dr. Briddon remarked that its sudden occurrence might be explained by a patent condition of the tubular vaginal process of the peritoneum, except at the internal ring, the partition at the latter point giving way and allowing the hernia to descend directly into the scrotum. But such herniæ were attended with grave symptoms from the first, and were difficult of reduction. He thought death in Dr. Howe's case was due to delay in the operation and to the injuries inflicted during taxis. As a rule, he thought taxis did harm in such cases, and that it was much better to perform the operation without delay.

Dr. Gibney asked if taxis was not usually attended with good results.

Dr. Briddon replied that he believed taxis, as a rule, did more harm than good in cases of strangulated hernia.

Dr. Howe believed in taxis before the operation, especially by the gravity method of Hamilton.

Dr. Ripley did not think that taxis should be abandoned because it had been abused. Every physician was in the habit of reducing strangulated herniæ by taxis, and the patients recovered. Sometimes ether was administered to that end, but not always.

Dr. Briddon said that he did not condemn the method, but the ignorant men who practised it.

Dr. Heinemann, in regard to the time which might elapse between the occurrence of a strangulated hernia and death therefrom, stated that he had performed an autopsy at the end of the eighth day of strangulation. The patient was brought into hospital at one o'clock of the day of his death and died three hours afterward, and after an operation had been attempted. A portion of the ileum was constricted, and one end of the gut was floating free in the abdominal cavity, and had discharged its contents in said cavity.

Dr. Peabody referred to the case of a gentleman with strangulated hernia who died after taxis had been employed. At the autopsy it was found that the peritoneum above the internal abdominal ring had been separated from the transversalis fascia, and more than a foot of the ileum had been forced into the space thus created. There was a tight constriction found at the neck of the sac.

EXSECTION OF ANKLE.

Dr. Howe presented a second specimen, consisting of two inches of carious tibia and fibula, with a small portion of the carious astragulus, which he re-

moved by exsection from a man, aged forty-four years, a patient in Charity Hospital. The disease was over a year's duration, and at the time of the operation the patient was much reduced by pain and suppurative discharge through openings in the neighborhood of the ankle. Notwithstanding his weakened condition the operation was performed with good result, the patient having a useful limb.

A FATTY OVARIAN CYST.

Dr. Garrigues presented a specimen of fatty deposit in an ovarian cyst. It was sent to him by Dr. Dawson, who had removed it after the patient's death. Only a portion of the cyst-wall could be obtained, but sufficient to show the condition named. The cyst itself was of the mixed variety. The fatty deposit was exclusively in the outer layer of the cyst, and was for the most part lobulated in character. At one point there was a diverticulum from the cyst-wall the size and shape of the finger of a glove. It presented an appearance worthy of note, and was of especial interest in regard to the question of its origin. Dr. Garrigues stated that he had not been able to find another case on record of adipose deposit in an ovarian cyst. Dr. Noeggerath had informed him that he (Dr. N.) had met with such a condition in ovaries removed by Battey's operation. He further remarked that ovaries covered with adipose tissue were normally found in the cat.

Dr. Briddon thought that the finger-like process was a secondary cyst which had become contracted.

Dr. Peabody remarked that the adipose tissue over the cyst-wall looked like that of portions of the omentum that might have become adherent.

Dr. Garrigues said that the tissue was positively not omentum, as there were no adhesions of the latter to the tumor found post-mortem. The elongated cyst was probably altered by contraction, but its shape was quite remarkable.

DIPHTHERIA AND ACUTE EMPHYSEMA OF LUNGS.

Dr. Tauszky presented the larynx and trachea of a child upon whom tracheotomy had been performed for membranous croup. The patient did well for twenty-four hours, when it was seen by Dr. Ripley who gave an unfavorable prognosis. The condition of the lung found corroborated the statement of Dr. Ripley, in regard to these cases, that they do not die of pneumonia, but of an extension of the membrane downward producing acute emphysema, or hyperinflation of the lung rather than consolidation.

Dr. Tauszky believed that the case was one of membranous croup rather than of diphtheria, as the submucous layer was not involved in the deposit. The specimen was, on motion, referred to the Microscopical Committee.

Dr. Peabody exhibited sections of the brain, liver, and kidney removed from the body of a patient who died in an attack of congestive pernicious remittent fever. The points of interest were the deep pigmentations to be seen along the lines of the vessels of the specimens and in the vessels themselves. Some of the latter vessels, especially in the brain, were completely filled with pigmented material.

Dr. Briddon presented a large interstitial fibroid of the uterus removed by abdominal section. This was accompanied with a written history (*vide* page 7).

TAPE-WORM.

Dr. Van Giesen exhibited a specimen of tape-worm which had been discharged from a German midwife who had used, according to his directions, the fluid extract of aspidium marginale. Not giving the doctor an opportunity of examining the fæces the head of the worm, which should have been in them, was not found. A teaspoonful of the following mixture was taken six times at intervals of every fifteen minutes: Fluid extract of aspidium marginale, ʒ ij., olive-oil, ʒ iv., sulph. ether, ʒ ss. This was followed by an active purge of castor-oil and croton-oil. The following morning the worm, measuring twenty-eight or thirty feet, was discharged.

DIPHTHERIA.

Dr. Van Giesen also presented a specimen of descending laryngeal diphtheria, which had been removed from a female child aged twenty-one months. He first saw the case October 20th. At that time the patient had a slight amount of what was conceded to be diphtheritic membrane in the lower part of the pharynx. She was otherwise comparatively well. There was no increase of temperature, and no great increase in the frequency of the pulse. The child apparently got better, and when there was no visible membrane in the pharynx, the case was dismissed simply with the precaution added, that the child might be taken worse at any time. On October 26th the patient became very hoarse, and was unable to make anything more than a whispering cry. The respiration was normal, the throat was very little reddened, and by a very prolonged examination nothing could be seen in the pharynx. The remedies which had already been prescribed were repeated. The breathing became much embarrassed on the 27th, and small doses of turpeth mineral were administered. The vomiting that followed the second dose brought up a membranous cast of the trachea (which was exhibited). The breathing was very much relieved, and inhalations of solution of bromine with small doses of the latter were given. The child died twenty hours after with symptoms of suffocation.

Dr. Van Giesen remarked, in conclusion, that he had been unable clinically, pathologically, or microscopically, to distinguish between diphtheria and membranous croup.

RETRO-PERITONEAL SARCOMA.

Dr. Heinemann exhibited a specimen of retro-peritoneal sarcoma, with the following history:

Mary Fischer, aged twenty-two years, New York, single. Family history good. Well up to one year ago, when exposure, just before a menstrual period, caused a permanent cessation of the menses. She subsequently complained of slight discomfort about the left lumbar region; continued in a rather uncertain state of health up to four months before death, when dyspnœa set in; she begun to fail and to suffer from disturbed digestion. She gradually became weaker, the dyspnœa became more severe, her abdomen enlarged, and rapidly within the last fortnight; ascites and slight jaundice followed. The urine was constantly loaded with urates. The patient was seen October 28th and November 5th by Dr. G. G. Wheelock, and was attended by Dr. Bleything. On account of the extensive dulness over the region of the spleen and the anæmia, it was thought a possible case of leucocythæmia, and when the subsequent rapid enlargement of the liver occurred, malignant disease of the liver was suspected. The patient died of asthenia, November 12, 1880.

Autopsy, made by Drs. Wheelock, Bleything, and myself. — Body moderately emaciated, jaundiced, marked prominence of epigastric region.

Heart and lungs normal. Liver, weight ten and

three-fourths pounds, extended above from the right third intercostal space to the lower border of the third rib on the left side, downward to the upper portion of the hypogastric region. The right lobe was enormously increased in size and invaded by numerous large and small new-growths. The left lobe was normal in size and contained a few small new-growths.

Stomach was small, and displaced toward the left; the transverse colon was pushed down to the hypogastric region. Spleen and kidneys were normal.

In the left lumbar region, and apparently intimately connected with the kidney, but subsequently found to be independent, is a large tumor weighing not quite four pounds, which, upon section, seems to be composed of small and large alveoli, filled with yellowish, firm, and in some places red marrow-like material, and infiltrated in parts with calcific deposit.

Mesenteric and lumbar glands were much enlarged and infiltrated.

Microscopic examination reveals the tumor to be a large-celled retro-peritoneal sarcoma.

DYSENTERY; SUPPURATIVE HEPATITIS; PERFORATION THROUGH INTO THE RIGHT PLEURAL CAVITY; PERICARDITIS AND PLEURISY WITH EFFUSION.

DR. SATTERTHWAITE presented the following case as an instance of hepatic disease dependent on dysentery, a condition which he was disposed to think was much more common in this latitude than was usually supposed:

H. V——, fourteen, office boy, was admitted into St. Luke's Hospital October 25, 1880. The history he gave was as follows: In July last he had an attack of "cholera morbus," which lasted about ten days. After feeling better he returned to his work, and for a week was able to attend to his regular duties. Then he was attacked with what was thought to be "dumb ague." He had chilly feelings, felt sleepy, and wanted to sit by the fire. After a while his breathing became difficult, and he had cough. In September last, about the middle, he began to have night-sweats, and he lost flesh. There was pain in the right side, of a dull character, shooting up to the corresponding shoulder. When admitted into the hospital the abdominal veins had become distinct, and the liver was found to be enlarged and tender. There was also some tympanitis, but no vomiting. Night-sweats continued. On November 8th the patient was taken suddenly with extreme dyspnœa. Dulness was found over the entire left side of the chest, and the left lung was œdematous. The patient died at 5.30 P.M. of the same day.

At the post-mortem examination the liver was found, by measurement, to be enlarged, and the seat of many abscesses, one of which had burst through the diaphragm and discharged into the right pleural cavity. Other abscesses, through their contiguity with the peritoneal cavity, had set up a peritonitis of subacute character.

In searching for the cause of the suppuration there was little difficulty in associating it with a concomitant lesion, viz., dysentery. The mucous membrane in the rectum, sigmoid flexure, and descending colon was marked by small ulcers that had nearly healed, and were evidently dysenteric in their nature.

The empyema, excited and augmented by the discharge of pus and necrotic tissue from the liver, had caused the right lung to be so compressed against the spinal column that the respiratory function upon that side was abolished. The sudden œdema of the opposite lung was thought to be similar in character to a like condition often observed in pneumonia, where, after an inflammatory process has been proceeding slowly within one pleural cavity, it suddenly shifts to the other, causing congestion, œdema, and often a rapidly fatal issue. An additional cause of sudden death in this case may have been the effusion within the pericardium and left pleural cavity, which added further to the difficulty of breathing.

Dr. Satterthwaite stated that recently he had seen several cases of hepatic suppuration, and had been induced to consult somewhat hurriedly the records of a few NewYork hospitals. In this way he had collected six cases from the St. Luke's, Presbyterian, and Mt. Sinai hospitals, and these, together with twenty-six from the Transactions of the Pathological Society, made a total of thirty-three fatal cases. From them it appeared that the most common cause that had been ascertained was dysentery; the next most frequent was associated with the irritation produced by the presence of calculi in the gall-bladder or biliary passages; medullary cancer, traumatism and operations in or about the pelvic fossa held more subordinate places. These statistics differed from the recent ones of Baerensprung, given by Thierfelder in the last number of "Ziemssen's Cyclopædia," where, in a total of 108, sixty-eight were associated with traumatisms, of which thirty were pyæmic. In other respects the statistics agreed in so far that affections along the line of the portal system held the next place in the rank of causes, and ulceration of bileducts the third position in order. Pyæmia was observed much less frequently in hospital practice than formerly, and hepatic abscesses of pyæmic origin were quite rare.

In the majority of cases (about two-thirds), the abscesses were single, and these were located, usually, in the right lobe. The most frequent assigned cause of death was peritonitis, due to an extension of the disease either from the liver or biliary system. Some urinary complication, to which the convenient name of Bright's disease was given, came in for an occasional cause of death—certainly albumen was by no means rare, and casts were occasionally found, while the specific gravity was apt to be low and suppression not infrequent at the final issue. In the present instance the rupture into the pleural cavity was a rare incident in the disease, though rupture into the lung was not so uncommon. While not infrequently there were no symptoms of the trouble, the following were found in a certain number of cases, and they are given in the order of relative frequency: 1, rigors and sweats, often under the name of "chills and fever;" 2, pain in the epigastrium; 3, jaundice; clay- or, occasionally, bronze-colored stools. Cerebral symptoms were only mentioned in one instance, and they were those of hypochondriasis simply. In same cases observed by Dr. S. there was an absolute destruction or necrosis of liver-substance, indicating a diffuse inflammation, rather than one that had distinct walls and contained pus. Aspiration had been resorted to in two cases and incision in one.

DR. CARPENTER thought that statistics tended to disprove the position and relation between dysentery and abscess of the liver.

Dr. SATTERTHWAITE replied that in this climate the rarity of the diseases precluded one from offering extended statistics. He believed that a causal relation existed often between hepatitis and dysentery, though in special epidemics the liver might not be implicated, as shown by Niemeyer during the last Franco-Prussian war.

The Society then went into Executive Session.

THE NEW YORK SOCIETY OF GERMAN PHYSICIANS.

Stated Meeting, November 26, 1880.

DR. NOEGGERATH, PRESIDENT, IN THE CHAIR.

THROUGH DRAINAGE IN EMPYEMA.

DR. HEINEMANN showed a little boy four years old, who served to illustrate the good results that may be obtained in intractable empyema by establishing through drainage. In the present instance there had been a history of progressive deterioration, until the simple incision originally made had been supplemented by a second one, each serving for the insertion of a drainage-tube. The antiseptic cleansings were now performed by the child's mother, and the case was apparently progressing to recovery.

DR. GERSTER called attention to the excellent results obtained by simple incision with consecutive drainage under strictly antiseptic precautions. König, of Göttingen, had recently again urged the utility of these measures. Lately Dr. Gerster had occasion to observe two cases of empyema, one occurring in an adult, the other in a child. In both cases simple incision had been followed by a rapid cure after a single irrigation. He also believed that if the operation were performed at a sufficiently early period, the lungs would always expand and primary pleural adhesions would appear. These events would facilitate the healing process and cut short an otherwise tedious course. Thick pseudo-membranes, as well as extensive and rigid pulmonary infiltration would, however, invariably interfere with rapid cures. In such cases the disease would take a course resembling that in simple drainage.

DR. JACOBI thought that the choice of a particular operative method would and should depend upon the nature of the individual case. He also took occasion to warn against early costal resections in children, because in them the pliable thorax would readily adapt itself to a more or less collapsed lung, without any such surgical interference.

DEEP LACERATED WOUND OF EYEBALL—SCLERAL SUTURE.

DR. OPPENHEIMER exhibited a patient on whom he had united by suture the edges of a penetrating wound of the bulbus oculi. The man was thirty-eight years old, and by trade a machinist. In June a foreign body had struck his eye and caused an extensive lacerated wound of the bulbus. There was prolapse of the iris, the anterior chamber was filled with blood, and the whole organ seemed flabby. The protruding portion of the iris was snipped off, and a scleral suture at once applied. The progress of the case was in every way favorable and altogether painless. In about four weeks the patient was discharged from the hospital. Two weeks later his vision was $\frac{20}{30}$ on the affected side. Recently a traumatic cataract had developed, but the visual field was apparently normal, at least as regarded the impression of light. One of the patient's eyelashes had found its way into the anterior chamber, where it had remained without causing the slightest irritation.

DR. GRUENING observed that scleral wounds were most dangerous in the ciliary region. Scleral sutures had been practised with success only quite recently. In this manipulation it was essential to avoid entangling the iris between the edges of the wound. Moreover, the sutures were not to be passed completely through the fibrous walls of the eye. Some writers even advised to pierce only the conjunctiva and the subconjunctival tissue.

CANCER AT THE ILEO-CÆCAL VALVE.

DR. GERSTER presented a specimen of the above with the following history: The patient had suffered from perityphlitic abscess due to intestinal perforation. Two weeks before the fatal issue a double incision was made and through drainage established. By irrigation large quantities of pus, fecal matter, and shreds of necrosed tissue were evacuated. But the patient's condition was only temporarily improved; he died soon after of septicæmia. Previous to the formation of the abscess the patient had presented only the symptoms of a chronic enteritis. The cause of his profuse purulent discharges was not detected until after death.

At the autopsy the small intestine in the right iliac region was found firmly united to the peritoneal covering of that region. The lower portion of the ileum was enormously distended and contained many hard fecal lumps. More or less deep intestinal ulceration and necrosis existed at this point. A cancerous ring was found to occupy the site of the ileo-cæcal valve, but there was no complete occlusion, a finger easily passing through the constricted portion. This fact, together with the exclusively fluid diet of the patient, explained why symptoms of intestinal obstruction had never been observed during the patient's sickness, which extended over a period of eleven months. Dr. Gerster believed that death had been due in large measure to the extensive intestinal ulceration and necrosis, brought about by the pressure of the hard fecal masses above mentioned. The doctor also referred to six other

CASES OF PERITYPHLITIC ABSCESS

which had come under his observation within the last three years. All these cases related to young persons, and one was that of a child. With regard to the etiology of the disease, he stated, that in one instance a foreign body had caused a perforation of the vermiform appendix. This case had presented unusual difficulties of diagnosis on account of its complication with a purulent coxitis of the right side. The hip-joint had become involved by extension along the iliac bursa. The patient, a young girl, died of erysipelas, which made its appearance some weeks after incision of the abscess. In the third fatal case an operation was refused and the patient died of peritonitis following perforation. In the child's case the disease had been caused by a kick against its belly. The cause of the abscess in the two remaining cases was unknown. Five operations (with two deaths, one in the cancer case, the second from erysipelas) were performed. Three times the operation had resulted in a complete cure. The incision was chosen according to Willard Parker's directions. Of the two cases not subjected to surgical interference one died of peritonitis, the other recovered under local applications of ice, but only after repeated rigors.

DIPHTHERITIC STENOSIS OF LARYNX.

DR. SEIBERT presented a specimen of the above removed from the body of a child aged six years. The patient had died of suffocation. Diphtheritic patches were not visible when the child was living; after death they were found at the posterior aspect of the soft palate. The case might have been mistaken for

one of genuine croup. He also showed a second specimen, consisting of a

FATTY HEART,

removed from the body of a woman who had suddenly died in the course of a croupous pneumonia. The right side of the heart showed the most extensive degeneration. The large glandular organs of the abdomen also showed adipose change. A microscopical examination had not yet been made.

Dr. Jacobi remarked that the immediate cause of death had probably been acute pulmonary œdema from lack of cardiac power.

Dr. Glueck had seen good results in such cases of threatening œdema, following the use of digitalis.

A discussion here ensued as to the precise nature of the lesion, whether fatty infiltration or fatty degeneration. Drs. Garrigues, Wendt, Jacobi, and Seibert expressed somewhat conflicting opinions. The matter was referred to a committee of one.

BLACK URINE IN ACUTE POISONING FROM CHLORATE OF POTASH.

Dr. Jacobi showed a sample of characteristically black urine, voided by a patient who had been poisoned by overdoses of chlorate of potash. A complete history would be given at a later meeting by Dr. Morjé.

PRIMARY CANCER OF THE LUNGS—SECONDARY MILIARY DEPOSITS OF KIDNEYS.

Dr. Wendt presented specimens of the above, which had been previously exhibited by Dr. Ripley at a meeting of the Pathological Society (see Medical Record, Dec. 18, 1880).

Dr. Heinemann said that about two years ago he had observed a case in many respects resembling the present one. Both lungs were affected. There were no secondary tumors in the kidneys. The symptoms had been about those of a dry pleurisy. The cancer had belonged to the medullary variety.

Dr. Seessel demonstrated a plaster-of-Paris cast, showing the cerebral lobes, fissures, and convolutions, together with the different psycho-motor centres at present known.

SPONTANEOUS GANGRENE OF TESTICLE.

Dr. Gerster presented this specimen, which he had removed by castration. The patient denied ever having received the least injury. Exploratory puncture revealed a chocolate-colored fluid, coming from the interior of the organ. Incision of the large tumor showed that the tunica vaginalis had become completely obliterated, and that the tunica albuginea was thickened to about six times its natural dimensions. The substance proper of the testicle was represented by a disintegrated crumbling mass, having a reddish-brown appearance, and resembling coffee-waste. There was no abnormal epididymis. The operation was successful, the patient quickly recovering from the castration.

Dr. Klotz referred to a case of

SYPHILITIC ELEPHANTIASIS OF THE LEG

which he had exhibited at a previous meeting of the Society. The extensive necroses of the soft coverings of the leg were ascribed to the existence of an arteriitis obliterans. Last October the patient began to complain of rheumatoid pains in the hitherto unaffected leg of the left side. This was rapidly followed by extensive gangrene of the soft parts, showing that here also the vascular affection previously diagnosed had occurred. The patient was now gradually sinking, with symptoms of slow septicæmia.

OVARIAN CYSTOMA FIRMLY UNITED TO BLADDER.

Dr. Noeggerath presented the above specimen, and gave the following account of it: On the 18th of October he had attempted the performance of an ovariotomy at Mt. Sinai Hospital. The operation could not be terminated, owing to the unusual complications of the case.

About three months before this time the ovarian cyst had been punctured, and it was observed that a small cyst, situated anteriorly to the principal tumor, completely collapsed and became invisible. During the subsequent ovariotomy this smaller sac was incised in the median line, and it was now ascertained to be the bladder, which was extensively and firmly adherent to the anterior abdominal parietes. The vesical wound was at once closed by sutures, and the ovarian tumor now attacked. After incision of the cyst, a sudden alarming hemorrhage took place, apparently proceeding from a solid growth springing from the internal surface of the cyst-walls. Rapid and profound collapse at once set in, and death was only averted by ligature *en masse* of the bleeding growth.

The ovarian tumor was so intimately united with the broad ligament of one side, and so firmly and extensively attached to the adjoining structures, that it soon became necessary to discontinue all further attempts at removal. Accordingly it was determined to try abdominal drainage of the cystic cavity. Eight hours after the cessation of the surgical interference, the patient's temperature had risen to 104° F. Rectal injections of quinine effected a temporary lowering, but soon the febrile movement was again pronounced, and at length, after about twenty-four hours, the patient succumbed in collapse.

At the autopsy the vesical suture was found to be perfect. Urine had at no time escaped into the peritoneal cavity (it had during life been removed hourly with the catheter). The most complete union existed between the adjoining walls of the ovarian cyst and the bladder.

A somewhat similar mishap had occurred to Dr. McLean, in Troy, N.Y., and quite recently Dr. Thomas had met such a case in his practice. His own case would therefore be the third, and these were the only American cases known to him.

Dr. Garrigues mentioned the fact that Ohlshausen had reported several instances in which the bladder had been cut into, the operator wishing to incise a cyst.

In answer to a question from Dr. Gerster, Dr. Noeggerath remarked that the diagnosis of such conditions was probably always impossible. Slight vesical troubles were the only symptoms produced by the anomaly. The introduction of instruments for purposes of vesical exploration would fail to furnish any clue to the existence of such complications.

Illinois Pharmacy Law.—Plans are making to secure a pharmacy law in Illinois. These plans are to be considered by a convention of Illinois druggists, which will be held in Springfield early in December. The draft of a law will then be submitted for revision and adoption. The call for this convention has been signed by over six hundred druggists, from which it may be presumed that the pharmaceutical profession is enthusiastic in its endorsement of such an act. —*Chicago Med. Review.*

NEW YORK SURGICAL SOCIETY.

Annual Meeting, November 9, 1880.

DR. H. B. SANDS, PRESIDENT, IN THE CHAIR.

TORTICOLLIS TREATED BY OPEN OPERATION.

DR. A. C. POST presented a male patient, seventeen years of age, upon whom he operated in April last for torticollis. It was a case of extreme rigidity, and had existed from early childhood. Great resistance was offered by both origins of the sterno-cleido-mastoid muscle. Some of his colleagues urged the subcutaneous operation, but Dr. Post was convinced that he could not safely make a full division of the resisting bands in that manner, and therefore made an open incision over the origins of the muscle. After dividing the prominent bands there was no yielding, and he continued to introduce the director under bands that could be felt with the finger, and in that way all resistance was removed. He applied a tent of horsehair dipped in a carbolized solution, 1 to 40, washed the wound with a solution of the same strength, and it healed substantially by first intention. The subsequent treatment consisted in the adjustment of a plaster-of-Paris jacket provided with hooks, to which artificial muscles (india-rubber), extending from a helmet applied to the head, could be attached. His chief reliance was upon an elastic band running in the course of the sound muscle. The patient wore the rubber muscles continuously for three or four weeks after the operation—at night only after the first month—and discontinued their use altogether at the end of two or three months. The result was a perfect cure, and no tendency to the return of the deformity had been manifested.

DR. BRIDDON remarked that he was one of the number who urged the subcutaneous section, but, after witnessing the operation, he was convinced that the subcutaneous method would not have given the result obtained. He should in the future recommend the open instead of the subcutaneous operation in similar cases.

FRACTURE OF THE INTERNAL EPICONDYLE OF THE HUMERUS.

DR. L. A. STIMSON presented the patient, the history of whose injury was given at the first stated meeting in October. [See RECORD, vol. xviii., p. 556.] The internal epicondyle was displaced so that its lower border almost reached the under border of the olecranon. The motions of pronation and supination were perfect, and flexion and extension were complete to within 10° of the normal range. One point in the history had heretofore been omitted, namely, when first observed his arm was fixed in a position of semi-extension, and it could not be moved until reduction of the supposed partial dislocation had been effected. He suggested that there was possibly a complete separation of the epiphysis at that time, plus fracture of the epicondyle.

DR. MARKOE remarked that if the case was one of simple fracture of the epicondyle there should not have been any difficulty in flexion or extension of the joint at any point or at any time. Moreover, if the case was simply an epitrochlear fracture there should not be, as there was, thickening of the entire internal condyle, and which corresponded to the condition that would be left after fracture of the internal condyle. Again, the supposition that fracture of the internal condyle had taken place, explained the thickening, and the limited flexion and extension which, slight to be sure, but nevertheless still existed.

DR. BRIDDON believed that a fracture involving the joint had occurred.

DR. T. T. SABINE then read a paper on

DIVISION OF THE LOWER JAW AS A PRELIMINARY OPERATION, AND A NEW METHOD OF DOING THE SAME.

DR. GEO. A. PETERS had reached the following conclusions with regard to the best method of dividing the jaw, after having practised it several times upon the cadaver: 1st, drill a hole through the centre of the bone at the point where the division was to be made; 2d, drill two other holes, one upon each side and half an inch distant from the central opening, with a view to the introduction of a piece of wire, by twisting which the coaptation is made secure. Then introduce a small saw into the central hole and divide the bone above and below to within one or two lines of its borders. Having done that, divide the remaining portions with bone-forceps, without leaving any rough edges. Be careful to use the saw upon both sides of the jaw before completing the section with the bone-forceps, as by doing so you will escape the inconvenience arising from movement of the fragments.

DR. MASON suggested that the tendency of the fragments to slip out of position after division could be easily overcome by the adjustment of a rubber dental splint, as in the treatment of fracture. He further remarked that he had seen attempts to remove growths from the floor of the mouth fail, because the surgeon did not have sufficient room to enable him to remove them as thoroughly as he could have done had section of the jaw been made.

DR. POST said that he had divided the lower jaw in two cases for the purpose of obtaining access to malignant growths. Both cases terminated fatally, but it was evident that the division of the jaw did not hasten the fatal result.

DR. MARKOE thought that all must agree concerning the facility which the operation afforded for getting at tumors in the floor of the mouth; for, in many cases, it was very manifest that the surgeon could not succeed in removing the entire mass except by performing the operation in that manner. But in a case in which he operated about eighteen months, a condition followed which surprised and annoyed him very much, and which hastened the inevitable fatal termination. The tumor was an extensive one, and a part of it was upon the inner face of the jaw-bone. The bone was divided in the median line, was subsequently wired together with all possible care; the wound healed over well, and for some time improvement took place. But presently a fetid material began to be discharged from the mouth, and it was evident that the disease was reproducing itself. On examination, it was found that the bone had not united, and it did not unite, and the two surfaces looking toward the mouth became a part of the diffused epithelial growth which finally destroyed life. The degree of disability was considerable, and was the chief cause of the morbid granulations.

Dr. Markoe also referred to a case in which the patient made a good recovery, and, by the help of a dentist, he was able to chew as well as ever. In that case he removed about an inch of the jaw-bone.

DR. POST referred to a case in the old New York Hospital in which fracture of the lower jaw was followed by great deformity, and Dr. Buck made a section of the bone, wired it together, and it united perfectly.

Dr. Sabine remarked that unless very great care was taken, muscular contraction would pull the fragments out of their proper position. He further remarked that he had not seen a case in which non-union had occurred after division of the jaw. An objection, however, which had been urged against the straight incision was that non-union was liable to follow.

Dr. Markoe suggested that the condition of the bone through which the surgeon was obliged to operate favored non-union, and destroyed the parallelism between such cases and those in which resection was made through healthy bone for other purposes.

Dr. Stimson suggested that the chances of union might be increased by putting the bone in a condition similar to that which existed when fracture occurred, namely: strip up the periosteum to some distance from the point at which the division was to be made, so that when the ends of the bone were brought together the periosteum would overlap, make a periosteal bridge, and thus facilitate the formation of callous. In most cases of fracture there was such a stripping up of the periosteum upon the one or the other side, constituting a periosteal bridge, that undoubtedly assisted the reparative process. If it was a fact that pseudo-arthrosis followed the operation in a certain number of cases, might not that proportion be reduced by such a modification?

Dr. Sabine remarked that non-union had occurred a sufficient number of times to cause some surgeons to discard the operation altogether.

Dr. Markoe asked, "What is the feeling of the members concerning the performance of the operation, particularly in cases of extensive cancer involving tissue behind the jaw: what has been the result: have they prolonged life, and have they effected any satisfactory cures?" So far as he was concerned he had become entirely discouraged with reference to gaining anything by the operation, and thought that he should not again operate in such cases.

The President remarked that he felt very much as Dr. Markoe did. In most cases in which division of the jaw was required, the disease could not be treated radically by the operation, because the infiltration would not allow of its thorough removal.

Dr. Briddon believed that the operation added to the patient's misery, and shortened his life.

Dr. Mason remarked that he was present at Dr. Sabine's operation, and felt confident that all of the disease was removed. He also believed that it could not have been removed satisfactorily if division of the jaw had not been made.

Dr. Sabine thought that if cases of that kind were to be thrown out as improper for operation, cancer should be excluded altogether; for certainly tumors about the mouth were met with which could be removed entirely if sufficient room was given.

The President remarked that he had never seen a case of cancer of the floor of the mouth that was distinctly circumscribed. All had had more or less distinctly the character of infiltrating cancer, and for that reason he had repeatedly refused to operate.

SHOULDER-JOINT DISLOCATION WITHOUT RUPTURE OF THE CAPSULE.

Dr. Stimson presented a specimen which was interesting on account of its novelty and because it did not present the lesions usually described as constant in the injury of which it was an illustration. A man, sixty-seven years old, fell from the fourth story of a building, and sustaining, besides other injuries, a dislocation of the left shoulder into the axilla. The symptoms as described to him were abduction of the arm, impossibility of adducting it sufficiently to bring the arm in contact with the trunk, or to permit the hand to be placed upon the head or chest, the head of the humerus could be felt distinctly on the axilla, and there was a marked depression under the acromion. Ether was administered and reduction was accomplished by making traction downward and outward, and direct pressure over the head of the bone. The man died on the eighth day in consequence of internal injuries caused by the fall. At autopsy it was found that there was no rupture of the capsule at any point, and the tendon of the subscapularis muscle was only partially torn through. The upper facet of the greater tuberosity had been torn off, and those were the only lesions which the joint presented. The descriptions given of the lesions following this accident always mentioned rupture of the capsule on the inside, and presentation of the head of the bone in the button-hole thus formed, and usually partial rupture of the tendon of the subscapularis. There was no history of a previous dislocation.

Dr. Markoe stated that fracture of the greater tuberosity was a common lesion in this accident; and referred to a case in which both shoulders were dislocated at the same time and both tuberosities were also broken off.

Dr. McBurney asked if the fact that the capsule was not ruptured was not evidence of incomplete dislocation. He had supposed that the capsule must of necessity be ruptured in order to permit complete dislocation.

The President remarked that that was the generally accepted opinion.

Dr. Stickler, house surgeon at the Presbyterian Hospital, on invitation stated that when the man, from whom the specimen was removed, was admitted, there was a depression under the acromion upon the side of the injury; that he could grasp the head of the bone distinctly in the axilla; that there was abduction of the arm; that he was unable to put the hand upon the opposite shoulder; and, at the same time, was unable to bring the arm to the side of the thorax. He reduced it in the manner described by Dr. Stimson, and the head of the bone slipped into place with the usual sensation and noise in such cases. It had been out about two hours when the man was admitted to the hospital.

A Gross Literary Piracy.—We learn from the *Medical News and Abstract* that a gross piracy has been made by certain English publishers of Mr. Presley Blakiston's "American Health Primers." The chief wrong they have done is to omit entirely the names of both editor and authors, and announce the series as "written and edited by distinguished members of the medical profession," thus misleading the British public into the belief that the books are of European and not American origin. To carry still farther this deception, they call them "Ward & Locke's Long-Life Series," as though it were an independent and original publication. In order to prevent the detection of this fraud from the various cis-Atlantic allusions, the books have been "carefully edited," which means that everything that could show they were American in origin has been cut out. This is piracy indeed. We hope that the English public will learn of it, and condemn it.

Correspondence.

TUCKER AGAINST NOYES.

To the Editor of The Medical Record.

My Dear Doctor—In further elucidation of the above lawsuit, to which you devoted an editorial in the Record for December 25th, will you permit me, first, to acknowledge the kindness of the remarks which were made in so far as they were personal to myself? Will you also permit me to quote from the charge of Judge Horace Russel various paragraphs which show what, in his judgment, is the real status of the medical man under the peculiar circumstances of such a case—both what are his rights, duties, and discretionary powers, and what are his limitations and liabilities?

I shall put various propositions into groups, that they may shed light upon each other. Permit me to follow, in the main, the order of your editorial comments. You say, "the whole point of the case turned upon the fact whether or no the surgeon was entitled to alter the order of his operations without additional and express permission from the parties or his nearest kin." I may, for the sake of accuracy, substitute the fuller form in which the Court puts the issue.

F. 695. "We come to what is conceded by all sides to be the vital question in this case, and that is, whether or not Dr. Noyes had authority or implied authority, or whether there was such a state of facts as that he was justified in believing, and did believe, that when Tucker returned to the infirmary on Friday, November 10th, he meant to submit himself to his (Dr. Noyes') judgment, for Dr. Noyes to proceed in accordance with his judgment, or whether Dr. Noyes was forbidden, under any circumstances, to touch the left eye, and had no reasonable right to believe that he was authorized to operate on that eye."—The judge remarked that the burden of proof rests on the plaintiff to show that Dr. Noyes was negligent in that he did not obey instructions. He then summed up the evidence.

There were two versions of the interview of the preceding Wednesday, and if the plaintiff was correct, to him belonged the verdict; if the defendant was right in his version (F. 703), "that to his final judgment as to what was right to be done, they (the Tuckers, four in number) made no response, but went their several ways, and returned (on Friday) saying no more, then you have a right to say he (Dr. Noyes) had implied authority to act in that case according to his best judgment. You have a right to say that, because sometimes there is an admission by silence." The judge then attempts to aid the jury in deciding between the two respective versions, and to determine the degree of credibility to be accorded to the opposing parties.

He also says (F. 701): "Now, gentlemen, this case turns upon which of these versions is substantially true. Was that one conversation or one interview so continuous and so connected that when they went their several ways on Wednesday Dr. Noyes understood, and was obliged to understand, and it was his duty to understand, that under no circumstances did Tucker propose to have an operation upon his left eye? Or, were there two interviews, at the first of which the Tuckers expressed their doubt, dissent, or opposition, and then, after the surgeon gave his final judgment as to what was best to be done, was there such silence on their part as to give him implied authority to use his best judgment, the judgment which he had expressed to them, or had they by their silence (if they did give him implied authority) given him the right to believe he had implied authority to pursue the case according to his best judgment? And it is according as you find the transactions of that day that the merits of the case rest."

To this annex one of the requests preferred by the defendant's counsel, viz., 3, F. 658, "that if the defendant had good reason, from what occurred in the presence of the plaintiff, to believe that he was authorized or employed by the plaintiff to operate upon his two eyes, the jury must regard it the same as if such authority was expressly given."—The Court: "That I charge: that is to say, that circumstances may create an implied authority which the law determines is just as good as an express authority."

F. 664. In reply to a request of defendant's counsel, the Court says: "The substance of that is, and I so charge, gentlemen, assuming that the defendant here was authorized to operate upon the two eyes of the plaintiff, or that the circumstances and conversations were such as that he had a fair right in reason, as between man and man, to assume from what had occurred that he was so authorized, then having proceeded upon the right eye to a point which, according to the testimony, did not amount to an operation, it was within the limits of his discretion as a surgeon to substitute the operation upon the left eye for the one which was intended then to be performed on the right eye."

F. 665, 11. Request to charge, by defendant's counsel, "That in the predicament so stated, the exercise of the discretion of the surgeon as to what was proper to be done was a professional question, to be determined by the defendant in good faith upon his own judgment, and he was not bound to consult the plaintiff's father or mother, or any other person, before proceeding to operate on the plaintiff's left eye." The Court: "That is correct if you also bear in mind that it is based upon the assumption that he had authority to operate on both eyes at all; although it was his intention first to operate upon the right and then upon the left—if he had authority to operate upon both, or implied authority, or the circumstances were such as that he fairly judged he had, he cannot be said to be negligent in assuming that the parties meant to give authority, and then this operation would not come within the rule of negligence."

On F. 683, 14. To a request by plaintiff's counsel, "That in determining whether or not the plaintiff intended or expressed such purpose on Wednesday, November 8th (*i. e.*, not to have an operation on his left eye), the jury have a right, it is their duty to consider not only what the plaintiff himself said, but what the plaintiff's father and mother said to or in the presence of the defendant." Court: "I think I have charged that substantially already. If not, I recharge it, provided the plaintiff accepted what the father and mother said, and treated as his act."

F. 681, 11. By plaintiff's counsel, "That the defendant cannot be justified or excused for the operation upon plaintiff's *left eye* unless one or the other of the following conditions existed: either, 1st, that the plaintiff requested, consented to, or otherwise

authorized it; or, 2d, that the plaintiff's conduct at and prior to the operation, fairly construed, misled the defendant with respect to his wishes and directions or consent." Court: "That I charge. And let me say, here is the very gist of the case."

F. 670, 18. By defendant's counsel: "That if the defendant was authorized to operate upon both the plaintiff's eyes, according to the prescription which he swears was given by him after the final examination on Wednesday, his authority in his professional discretion in the emergency which arose upon the attempted operation on the right eye to substitute an immediate operation on the left eye was not controlled or qualified by the remark alleged by the plaintiff to have been made by him after taking his place upon the operating-table." Court: "That I charge."

It would take too much space to present other points which were discussed and passed upon. The case was submitted to the jury to decide whether or not the interview of Wednesday, in all its parts—that in which both plaintiff and defendant substantially agreed, and that to which plaintiff and his friends (four witnesses) omitted to narrate—gave defendant authority to operate on both eyes.

The court had ruled that under the special emergency which arose, it was clearly within the surgeon's professional discretion to substitute the actual operation on the left eye for the intended and not completed operation on the right eye—and he was not bound if he had already gained the needful authority to treat both eyes, to again consult the patient's kin or himself.

On the question submitted to them the jury gave two votes for the plaintiff Tucker, and ten votes for the defendant Noyes. Of the two jurors who were for the plaintiff one declared that he would go with the majority if the other would.

Now, Mr. Editor, I do not object to the rule of prudence in securing from patients and their friends the most undoubted and express authority for our professional conduct when we are to treat them surgically or otherwise. I consider it most wise and needful to do so. I certainly have no wish to involve myself again in such vexatious and unprofitable experiences as I have lately undergone. But I have given rise to a judicial expression of opinion which sets our profession upon high ground of right, duty and responsibility, and defends us from attacks founded on ignorance and possibly on worse motives. If I was by consent of all sides vindicated in my professional and personal character, I have gained what was first in my desire, but besides that the profession has been set upon a surer footing in its relations to dissatisfied and litigious patients.

The limitation and liabilities of medical men are set forth by Judge Russel in clear terms, and are not different from those which we already observe and practise. They are that a patient must give consent to any operation, and whether one organ or member, or two, shall be operated on, etc. It was also in this case decided by the court, that advantage to sight unexpectedly gained in the right eye could not be counted as an offset to injury incurred by loss of the left eye in case the operation on the left were decided to be unauthorized. He also said that the defendant could not be held responsible for any ulterior impairment in sight of the right eye from the good condition which it enjoyed for a year or more.

Very respectfully yours,
HENRY D. NOYES.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 19, 1880, to December 25, 1880.

BAILY, J. C., Major and Surgeon. Granted leave of absence for one month, with permission to leave the limits of the Division, and apply for one month's extension. S. O. 188, Division of the Pacific and Department of California, December 13, 1880.

HEIZMANN, CHAS. L., Capt. and Asst. Surgeon. The extension of his leave of absence granted him October 30, 1880, from A. G. O., still further extended two months. S. O. 268, A. G. O., December 18, 1880.

KANE, J. J., First Lieut. and Asst. Surgeon. Relieved from duty at Fort Cummings, and assigned to duty as Post Surgeon at Fort Union, N. M. S. O. 153, District of New Mexico, December 13, 1880.

LOUISVILLE, ITS COLLEGES AND DOCTORS.—A correspondent of the *Cincinnati Lancet and Clinic*, in reporting the meeting of the Tri-State Medical Society at Louisville, says:

"Louisville is noted for its doctors' quarrels and jealousies, which prevent the members of the profession from working together in a body on such an occasion as the meeting of state societies. One of the journals barely referred to the coming session. . . .

"The medical colleges here cannot be said to be in a prosperous condition this winter. All the Louisville medical schools agreed last summer to increase the fee for a course of lectures to seventy-five dollars, thus making it uniform with the fees in Cincinnati and Chicago. This was not done, however, without a previous consultation with the authorities of the Nashville colleges, who agreed to adopt the same figures. It is charged at Louisville that the Nashville professors waited until after the Louisville announcements for 1880–81 had been sent out, and then issued their own, putting the price of tuition at the old figures. Without venturing to state whether or not this is the correct presentation of the case, the fact remains that this winter the Nashville colleges have low fees and large classes, and the Louisville schools the reverse. Persons generally can scarcely appreciate the great influence this matter of a few dollars has upon the average medical student in his choice of a college."

THE "BLOWING WRINKLE."—DR. W. W. Gayle, of Hancock, Md., writes: "In your edition of November 27th, Dr. Hutton gives a new method for the resus-

citation of asphyxiated new-born infants, the 'blowing wrinkle' as he calls it. I am a young practitioner, and in the country at that, but I have seen three such cases as the doctor speaks of in my practice, and have used the blowing method every time with success. While I have never read anything on this subject (*i.e.*, blowing) I did not consider it new. I cannot give Dr. Hutton the credit of this discovery."

Case of Poisoning from Poke-Berries.—Dr. John R. Hilsman, of Trezevant, Tenn., writes: "I was called October 10, 1880, to see a child two years old, poisoned by poke-berries eaten about night the evening before; quantity not known. The parents noticed at the time its hands and face stained, and also some of the berries in mouth, but did not know the danger, and did nothing. It ate a hearty meal soon after and seemed as well as usual till bed-time, and, in fact, seemed exhilarated. During the night the child became restless, and early the next morning it was noticed that it could not see, and the power of supporting head was lost, and the muscles generally were relaxed. I was at once sent for but did not arrive till 3 P.M., at which time breathing was rapid and superficial, and heart's action feeble and rapid, pupils dilated, and extremities cold. Before I had time to prescribe the child was seized with a severe spasm, lasting fifteen or twenty minutes. Cold was applied to head, and mustard to spine and extremities. Atropia and ether were given hypodermically to stimulate heart and respiration. After spasm was relieved and heart acting better, purgatives and enemas were given to remove from bowels what might remain of berries. The seed and hulls of a number were discharged per rectum. The diapers for several days were stained with their coloring matter. The secondary effect of the poison was irritation of bowels and stomach, coming on about thirty-six hours after berries were eaten, and lasting several days, causing considerable fever. As soon as the child was revived enough to notice, it seemed to be tormented with a continual itching of skin, and about the fourth day was covered with patches of urticaria. I supposed this to be due to the poison in blood, as we well know how irritating the poke is when applied locally, producing a terrible itching, wheals, etc. I have been able to find very little concerning this poison and its antidotes in journals and books. I suppose the cause of the delay in the symptoms of poisoning was due to a hearty meal being eaten soon after the berries were taken."

"Study" of a Fashionable New York Physician.—In Mr. Henry James's recently published novel, "Washington Square," there is a very clever character study of a fashionable physician. The gentleman who is presented as a type of this class is a Dr. Sloper. He has that mixture of talent, perspicacity and adaptation which insures success in almost any profession. Starting life in a humble fashion, he both marries a fortune and makes a fortune, and this without any sacrifice of his own self-respect or resort to charlatanry. He is simply a profound student of human nature, and sees no reason why he should not humor it while endeavoring to benefit it. Mr. James says:

"It was an element in Doctor Sloper's reputation that his learning and his skill were very evenly balanced; he was what you might call a scholarly doctor, and yet there was nothing abstract in his remedies—he always ordered you to take something. Though he was felt to be extremely thorough, he was not uncomfortably theoretic; and if he sometimes explained matters rather more minutely than might seem of use to the patient, he never went so far (like some practitioners one has heard of) as to trust to the explanation alone, but always left behind him an inscrutable prescription. There were some doctors that left the prescription without offering any explanation at all; and he did not belong to that class either, which was, after all, the most vulgar. It will be seen that I am describing a clever man, and this is really the reason why Doctor Sloper had become a local celebrity."

No doubt many will recognize some very familiar traits in the above sketch. There is this to be said, however, about New York's fashionable physicians: in the regular school they hardly have the prominence in numbers or position that they possessed in the time of which Mr. James writes. Proportionally the number of physicians of the Dr. Sloper type (considerably diluted) is now much greater among the quasi-homœopaths—those who, under the guise of a broad eclecticism, profess whichever medical dogma suits their patient best. They are persons generally who excel in their powers of adaptation to the idiosyncrasies of woman.

Among regular practitioners the development of the specialties, as well as the greater infusion of the scientific spirit, has brought new elements into the problem of professional success. A consulting or specialist practice now appears to most persons a much more desirable thing than a fashionable one, and for the former there is required more study of disease and less of human nature *per se*.

Test for Sugar in the Urine.—Dr. L. S. Oppenheimer (*Louisville Medical News*) gives the following:

℞. Cupr. sulph. cryst. ..... gr. ℔.
Glycerin purif. ..... ℥ j.
M.

One drachm of this mixture will reduce one grain of grape-sugar in a caustic alkali. Two or three drops of the mixture are put in a test-tube and ℥ ss. liq. potas. added; the whole is then boiled, a few drops of urine added and the whole boiled again. If sugar is present it will be thrown down as the brownish-yellow cuprous oxide. The test is surer than Trommer's, it can be used to determine the quantity of sugar, albumen does not interfere with the reaction, and the mixture will keep indefinitely.

A National Cattle Commission.—Secretary Sherman, in his annual report just made to the President, says that the order of the Privy Council of Great Britain, ordering all American cattle to be slaughtered within ten days after reaching England, is working great injury to our cattle dealers. The order was made to guard against the introduction of pleuro-pneumonia. If that disease could be "stamped out" of this country, doubtless the order would be rescinded. The Secretary, therefore, recommends the creation of a commission which shall investigate the disease, co-operate with local authorities, and establish quarantine stations, and regulations, if necessary.

Army Medical Museum.—The President's message contains the following statements regarding the Army Medical Museum. The facts are given in connection with a recommendation to Congress to complete the fire-proof building for the War Department:

"The collections of books, specimens, and records constituting the Army Medical Museum and Library are of national importance. The library now contains about 51,500 volumes and 57,000 pamphlets relating to medicine, surgery, and allied topics. The

contents of the Army Medical Museum consist of 22,000 specimens, and are unique in the completeness with which both military surgery and the diseases of armies are illustrated. Their destruction would be an irreparable loss, not only to the United States, but to the world."

THE INFLUENCE OF HIGH ALTITUDE ON SEXUAL APPETITE, SLEEP, AND RESPIRATION.—Dr. W. P. Shoemaker, of this city, writes: "Among the many peculiarities of high altitudes, not the least interesting is the loss of sexual desire, and often of sexual power, experienced by those who ascend the mountains. Especially is this so of Colorado. The effect is not universal, but it is the rule, and I am inclined to think that all feel the effect to a certain extent. A man may live for years there, and never, either sleeping or waking, will he have the least sexual desire. I have known men to go to houses of prostitution by force of habit, and not even the combined influence of wine and women could arouse his dormant passion. But others have the ability or power, yet lack the desire, unless brought in close proximity to the exciting cause. I have known men whose thoughts by day and whose dreams by night were lust when in a low altitude, to lose all desire immediately on ascending the mountain, and have a return of the trouble as soon they descended. I will not attempt any explanation of this anaphrodisiac property. This influence is confined to men, and it has even a reverse effect on women, which makes an explanation more difficult than if the influence were general. The natives have a superstition there that it is due to the waters of a certain stream, the crossing of which renders him who has the audacity to invade their country impotent; and they give this stream a name which is significant of its supposed function. Is it not a rational presumption to hope that this feature of the climate might be utilized in the treatment of certain nervous affections which have their origin in a diseased condition of the sexual organs?

"The soporific quality of the atmosphere is another peculiarity of the climate. This quality is very different from the drowsy, languid feeling which a sea-air produces during the day. The sleep is simply deeper, more profound, and about two hours longer. You go to bed at your usual hour, and neither noise nor light will awake you, perhaps until 10 A.M. This is a pretty general effect upon the "tenderfoot," as they call visitors. I have seen great relief given to patients suffering from hyperæmia of the brain and the sleeplessness which attends that condition so generally; but I am sorry to say that the benefit afforded these cases is not permanent, but a return of the symptoms present themselves as soon as the patient returns to the low altitude. I might say that it is not necessary for a patient to go to a great elevation to experience this effect. Colorado Springs is sufficiently high to produce it, but to a less marked degree than the higher localities. A sense of exhaustion is felt on the least exercise, and this appears to be due to a lack of oxygen in the system. Until the auxiliary respiratory muscles have learned to perform their duty perfectly, the lungs cannot inhale sufficient air to keep up the demand for oxygen. In a few days the auxiliary respiratory muscles become sore, just as any other muscles will do when first they perform their functions. The respirations are increased in number, and the pulse is increased in rapidity and force, but the temperature remains the same. Frequently blood will be expectorated from the mucous membranes of the organs of respiration, the skin becomes dry, and the lips chap. The latter are due to the dryness of the air. It is not difficult for us to see that this would be a good place for the man who has a cavity, a hemorrhage, or any solidification to come from; but it is difficult for us to see what class of patients it would benefit who have lung trouble. Certainly not bronchitis, for it will produce that in a healthy lung. It would be death to a man suffering from emphysema, or any form of lung trouble which had its cause in cardiac disease, for the heart becomes an uncontrollable organ under these conditions. As a prophylactic to consumption I think nothing could be more desirable.

"So thoroughly and forcibly opening up the alveoli, it will prevent the accumulation of epithelial cells, fibrinous exudations, and leucocytes within the alveoli and bronchioles; or it may even help to clear out these accumulations before there is any thickening of the walls of the terminal bronchioles or an increase of interlobular connective tissue. But in the advanced stages of phthisis, nothing could be more irrational than to expect benefit from that climate. Always remember that, although the chemist may tell you that there is a greater per cent. of oxygen in that atmosphere, that owing to its less density, there is very much less in a cubic foot than in our own climate."

THE HUDSON COUNTY CLINICAL SOCIETY of New Jersey has been organized with the following officers: President, T. R. Varick, M.D.; Vice-President, C. W. Cropper, M.D.; Treasurer, L. J. Gordon, M.D.; Secretary, A. C. Hoffman, M.D.; Recorder, F. G. Golding, M.D.

THE "HAMMOND PRIZE" OF THE AMERICAN NEUROLOGICAL ASSOCIATION.—The American Neurological Association offers a prize of five hundred dollars, to be known as the "William A. Hammond Prize," and to be awarded at the meeting in June, 1882, to the author of the best essay on the *Functions of the Thalamus in Man*. The conditions under which the prize is to be awarded are as follows: 1. The prize is open to competitors of all nationalities. 2. The essays are to be based upon original observations and experiments on man and the lower animals. 3. The competing essays must be written in the English, French, or German language; if in the last, the manuscript is to be in the Italian handwriting. 4. Essays are to be sent (postage prepaid) to the Secretary of the Prize Committee, Dr. E. C. Seguin, 41 West Twentieth Street, New York City, on or before February 1, 1882; each essay to be marked by a distinctive device or motto, and accompanied by a sealed envelope bearing the same device or motto, and containing the author's visiting card. 5. The successful essay will be the property of the Association, which will assume the care of its publication. 6. Any intimation tending to reveal the authorship of any of the essays submitted, whether directly or indirectly conveyed to the Committee or to any member thereof, shall exclude the essay from competition. 7. The award of the prize will be announced by the undersigned Committee; and will be publicly declared by the President of the Association at the meeting in June, 1882. 8. The amount of the prize will be given to the successful competitor in gold coin of the United States, or, if he prefer it, in the shape of a gold medal bearing a suitable device and inscription.

Original Lectures.

SERO-FIBRINOUS PLEURISY.

A Lecture,

By A. L. LOOMIS, M.D.,

PROFESSOR OF PATHOLOGY AND PRACTICE OF MEDICINE IN THE UNIVERSITY MEDICAL COLLEGE, NEW YORK.

(Reported for The Medical Record.)

PART I.

I pass to-day, gentlemen, to the history of another form of pleurisy. Sero-fibrinous pleurisy is, perhaps, a better term by which to designate it than subacute pleurisy. In this form of pleurisy there is a large amount of serous effusion and very little lymphy exudation. The pleural cavity is more or less completely filled with fluid which contains flocculi of lymph and a few cells. The cells are not abundant, the plastic material is not abundant. The serous effusion stamps the character of the inflammatory process. The most important pathological change which takes place in this form of pleurisy, however, is not found in the character of the exudation, but in the pleura itself.

In giving you the history of acute pleurisy I told you that the exudation is upon the free surface of the pleura, and that it is of a cellular, fibrinous, and serous character. The same kind of exudation occurs in sero-fibrinous pleurisy, but there is a very different condition of the pleura itself. The pleural membrane, as far as the inflammatory process has extended, will be found thickened. New connective-tissue developments have taken place, and it is this which characterizes the pathological change in this form of pleurisy. This thickening of the pleural membrane may occur both in the costal and the pulmonary pleura. It is progressive so long as the fluid remains in the pleural cavity. I have seen the pleural membrane thus thickened to the extent of half an inch. This thick, firm, indurated pleura, especially if the pulmonary pleura is extensively involved, interferes with the expansion of the compressed lung, when the fluid is removed; therefore, it is important that the serous effusion shall be removed from the pleural cavity as soon as possible. The longer the fluid remains in the pleural cavity the greater will be the pleuritic thickening and the more imperfect the expansion of the lung afterward.

If the sero-fibrinous exudation shall completely fill the pleural cavity the lung will be compressed against the spinal column, as is represented in this diagram. The diaphragm will be pushed down below its normal limits, and the liver and heart will be pushed out of position. If the pleurisy occur on the left side the heart will be pushed to the right, perhaps so far that the apex-beat will be felt under the right nipple. If it occur on the right side the heart will be pushed to the left. The amount of displacement of the viscera in the thoracic and abdominal cavities will, of course, depend upon the amount of the effusion into the pleural cavity. In extreme cases the intercostal spaces will be pushed outward. The compressed lung will have a peculiar tough, elastic feel. It is not like consolidated lung, but it has a firm, leathery feel. The lung in this condition is called carnified lung. The compression which produces it may be caused by a tumor or by fluid effusion into the pleural cavity. Not only is the lung-tissue compressed under these circumstances, but also the bronchial tubes, unless there shall be induration of the bronchial walls or of the lung-tissue around them are consolidated from some old inflammatory process, in which case the bronchial tubes will remain open and air will enter them with each inspiration, and the sound produced by its entrance will be transmitted to the surface of the chest, and you will have bronchial respiration. Therefore, please remember that in certain cases of pleurisy, in which the cavity of the pleura is completely filled with fluid, you will have bronchial respiration over the surface of the fluid, but the rule is that when the pleural cavity is filled with fluid you will not have bronchial respiration over the affected side.

If recovery is to take place, the fluid after a time is absorbed, and the fibrinous material which floats in the fluid undergoes degeneration, becomes liquefied, and is also absorbed. But absorption of the fluid will not take place if the distention of the pleural cavity be so great as to occlude by pressure the pleural and subpleural vessels, for it is through these vessels that the absorption, to a great extent, is effected. If the distention of the pleural cavity is not great, and the vital powers of the patient are not greatly depressed, all the fluid and plastic material will be absorbed and the two surfaces of the pleura will again come together.

But observe what has happened. The lung has been compressed for one or two, or, more likely, eight or ten weeks, or perhaps three or four months, and the lung is imperfectly expanded or expands with difficulty, the difficulty is increased in proportion to the firmness and perfection of the newly formed tissue in the pulmonary pleura. Then, if the fluid disappears from the pleural cavity and the lung cannot expand to take its place, the walls of the chest must retract and the thoracic and abdominal viscera will be displaced to fill the cavity.

Now, as the two surfaces of the pleura come together, they become more or less adherent to each other, the extent of the adhesions depending upon the activity of the connective-tissue formations. If it is soft and plastic, and is developing rapidly, quite firm adhesions will take place between the two pleural surfaces. They may become agglutinated to each other throughout their entire extent. As the lung cannot expand to its normal limits, the viscera are displaced to a greater or less degree: as a consequence, there is more or less deformity, especially if the pleurisy occurs in early life. After a time the adhesions may disappear, and nothing will remain but the thickened pleura.

Etiology.—Sero-fibrinous pleurisy does not occur as a primary affection. It is rarely, if ever, idiopathic. It comes on in the course of some other disease, or during the existence of some condition which has interfered with the nutritive powers of the individual. It occurs perhaps more frequently in connection with chronic Bright's disease than with any other form of disease, unless it may be with chronic disease of the lung-tissue. It is especially liable to occur in the course of chronic phthisis. When it occurs in the course of Bright's disease, it is usually in that form in which there is a good deal of interstitial change in the kidney, which is likely to be associated with a rheumatic or gouty diathesis, or with interstitial changes in other parts of the body.

It also occurs in connection with chronic lung diseases. One who has a chronic catarrhal pneumonia is very liable to have a localized pleurisy, and this

pleurisy is most likely to be of the sero-fibrinous variety.

Then it unquestionably occurs as a result of what I suppose may be called a predisposition of the system to tubercular inflammation. I have yet to see tubercular disease of the lung independent of tubercular developments in the pleura. My impression is that the tubercular developments occur, in such cases, primarily in the pleura. I am of opinion that in those cases of sero-fibrinous pleurisy where the patient does not get well, but passes into phthisis, careful investigation will show that tubercular inflammation was the beginning of the pleuritic changes—that is, from the commencement of the inflammation of the pleura, tubercular formations have taken place in its substance. The connection between this form of pleurisy and phthisis is very close. When a patient with a phthisical appearance, and who has a phthisical diathesis, comes to me, and I find he has sero-fibrinous pleurisy, as evidenced by fluid in the pleural cavity, I am very careful about my prognosis, for it is more than likely that he has a tubercular inflammation of the pleura. I believe it is possible to have a local tubercular inflammation of the pleura without there being tubercular developments in any other part of the body; and I believe that in almost all, if not in all, the cases where tubercle is developed in the lung, there has been previous tubercular inflammation of the pleura. The signs of this tubercular inflammation of the pleura are often a sero-fibrinous effusion into the pleural cavity, etc. Gentlemen, I wish to make myself clear upon this point and not be misunderstood. I shall later in the course speak of tuberculosis as an infectious disease, and class it among the blood diseases, and shall raise the question of its contagion. In that case, however, I shall refer to acute tuberculosis, which is always accompanied by constitutional symptoms of an unmistakable character, which are active in their development, rapid in their course, and which terminate fatally. But I am *now* speaking of a localized tubercular inflammation. I am not clear on this point, whether the pathological changes which occur in acute tuberculosis be the same as those in localized tubercular inflammation, or whether tubercles of the same microscopical appearance may not differ in their nature. To make myself clear to you, take syphilis for illustration. Two persons have a chancre: one, by proper treatment, suffers little from it, possibly gets well; the other, in spite of all you can do to prevent it, passes rapidly to the last extreme of syphilitic disease. So in the disease before us: here is a tuberculosis which occurs in connection with a constitutional infection which goes straight on to death. Here is another localized tubercular development which cannot be distinguished by its anatomical outlines or elements from the former, which is simply a local inflammation of the pleura, attended by serous effusion into the pleural cavity, which may possibly be recovered from.

Symptoms.—This form of pleurisy is ushered in by mild rather than by severe symptoms. It is rarely, if ever, ushered in by a distinct chill. Even pain in the side is not a prominent or a constant symptom. It comes on often so insidiously that the patient will not be aware of the time of its commencement. When you question him closely he will, perhaps, say that three, four, five, or six weeks before, he had a little pain in the side, and he noticed that there was an uneasy sensation there after exercise; but there will not be that sharp pain which attends acute pleurisy. He will have noticed, also, that for five or six weeks he has been losing strength, yet if his usual avocation require but slight physical labor he will be able to attend to its duties. He will have noticed, also, that he is paler than usual, that he has lost flesh and strength. The palms of his hands have been hot at night, and yet there has been no distinct fever; there has been no chill; there have been no sharp ushering-in symptoms which ordinarily attend the development of grave disease. When he consults you the only symptoms that you will notice will probably be this pallor of countenance, this loss of flesh, this anxious expression. The most prominent symptom which you will notice will be his shortness of breath, which is increased by the slightest exercise. While he is telling you his history he will stop and catch his breath, making his sentences short and interrupted. But none of these symptoms are characteristic of this affection alone. They simply point to a grave disease of some kind, so situated as to interfere with the respiration. The patient will, in all probability have a cough, but there will be very little expectoration. Not infrequently the only general symptoms are those of advanced phthisis.

It occasionally happens that sero-fibrinous pleurisy is ushered in by very active symptoms, symptoms as active as those that usher in acute pleurisy: there is pain in the side, a catching respiration, perhaps a chill, and so on. These symptoms continue for a time, and then the patient apparently is recovering, and perhaps, after two or three weeks, he will seem to be quite well, but upon examining the chest you will find a large amount of fluid in the pleural cavity. The disease was ushered in like an acute pleurisy, but, instead of going through the usual stages of acute pleurisy, and ending in absorption and adhesions, as occurs in acute pleurisy, the fluid remains in the pleural cavity four or five weeks, although, perhaps, small in amount. All rational symptoms may disappear, and you may think the patient is doing well, and promise him a recovery, but suddenly he is seized with great dyspnœa; he is unable to lie down, his countenance is suffused, the capillary circulation is imperfect, and so on. In this condition he sends for you, and you will find that his pleural cavity has suddenly become distended with fluid, and he demands immediate relief. Such patients may die suddenly, from the sudden fluid accumulation. I have occasionally seen patients brought into the hospital with a pleural cavity filled with fluid, with œdema of the lung on the opposite side, with all the signs of impending suffocation. This form of sero fibrinous pleurisy, which is ushered in with acute symptoms, is an exceptional form; it does not occur often. As a rule the disease is developed insidiously, so far as the rational symptoms are concerned, but the physical signs are very clear.

There is, perhaps, no disease of the lungs, unless it be emphysema, in which the physical signs are so easily appreciated as in sero-fibrinous pleurisy, where the pleural cavity is filled with fluid. If it be only partially filled with fluid, the same rules will govern you in its appreciation as I gave in connection with the history of acute pleurisy. If the pleural cavity be distended with fluid, as is represented in this diagram, the physical signs and their importance will change very much. Under such circumstances *inspection* will show that the affected side is increased in size in every direction. It will be increased upward, laterally, and downward, and you will notice bulging of the intercostal spaces on the affected side. The respiratory movements of the affected side will

not be noticed, for the reason that the cavity is distended with fluid. The heart will be found pushed out of its normal position, and the apex-beat will be noticed either to the right or left of its normal position, according as the pleurisy is upon the right or left side. There will be bulging and enlargement of the abdominal cavity, and if the right pleura be the seat of the effusion the liver will be pushed downward, below the free border of the ribs. As you grasp the two sides with your hands you will notice very little movement upon the affected side, while upon the other the expansive movement will be greater than normal. There will be absence of vocal fremitus over the seat of the effusion. This is the rule, but you know there are exceptions to all rules. If, as I described to you before, there be an open bronchial tube leading through the compressed lung into the centre of the fluid effusion, vocal fremitus may be increased. It has therefore been said by some that the absence of vocal fremitus in sero-fibrinous pleurisy is not so important a physical sign as has been claimed, but, gentlemen, whenever you get vocal fremitus below the level of the fluid in sero-fibrinous pleurisy, you may know that there is some unusual arrangement in the chest-cavity; that, for instance, the lung with a bronchial tube leading into it has not been compressed against the spinal column, as is usually the case, or that the lung is bound by old adhesions to the chest-wall; under such circumstances vocal fremitus may be increased below the pleuritic effusion. Again, as said before, if a bronchial tube shall not collapse on account of hardening from previous inflammation, the vibrations will be conducted through it to the surface of the chest, and, as represented in this diagram, you will detect vocal fremitus over the scapula behind, while below the scapula there will be absence of vocal fremitus. A knowledge of acoustic laws will enable you to readily understand how vibrations which are carried to the centre of the pleuritic effusion shall be transmitted to the surface of the chest. You may not be able to hear the sound produced by striking two stones together under water while your head is above the surface, but when you place your head under the water you will hear the sound very distinctly, even at a considerable distance. The same law holds true when vibrations of air are carried into the centre of a serous effusion in the pleural cavity.

Percussion will give flatness over all that portion of the pleura filled with the effusion. If the cavity be full a change of position will not change the line of flatness. In this event the flatness will extend below and to the right or left of the normal limits of the affected pleura, according as the effusion may be upon the right or the left side.

Auscultation, as a rule, gives entire absence of respiratory and vocal sound over the seat of the effusion, but there may also be exceptions to this rule. You can very readily see why there is absence of the respiratory murmur. I am not now speaking of the vesicular murmur alone, but also of the bronchial, both of which elements are included under the term respiratory murmur. As a rule both will be lost, but if, as said before, a bronchial tube shall remain open in the centre of the fluid, as for instance here in the diagram, bronchial respiration will be heard at this point over the fluid. Please remember this exception, for farther along in the course you will learn that bronchial respiration along with dulness on percussion is a sign of pulmonary consolidation. I remember of once being called in consultation by a physician who had rested his diagnosis of pulmonary consolidation upon the existence of bronchial respiration. He heard bronchial breathing behind, and supposed the patient had pneumonia which had existed for six weeks; he could not understand why the pneumonia did not resolve. When I introduced an exploring trochar into the pleural cavity, and drew off fluid, he could hardly believe that it came from the pleural cavity, for he had the idea firmly impressed upon his mind (perhaps when a student) that bronchial respiration always was a sign of pulmonary consolidation.

In the next stage, when absorption shall take place, inspection will show a gradual disappearance of the bulging on the affected side, the displaced organs will gradually return to their normal position, there will be some motion on the affected side. If the fluid has remained in the pleural cavity for a long time you will notice after its absorption some falling in of the affected side, the reason for which has already been given. Not only will inspection show loss of motion on the affected side, palpation will do the same, and will also show either an absence or a marked diminution in vocal fremitus.

Percussion will show no longer flatness, but dulness. The lung has expanded, but the pleura is thickened, and this new tissue thickening renders the lung more solid than normally, and in consequence of these facts there is dulness on percussion. This dulness will be noted over the entire pleural cavity, more marked, however, over the lower than over the upper portion.

Auscultation will give feeble respiration. The respiratory sound will be heard as it were at a distance; it will not seem to be near your ear, and will be less intense than normal, but still it is vesicular in character. The respiration, though feeble, still retaining its vesicular quality, will enable you to differentiate between this condition and the condition of the lung, due to fibrous induration. In the latter case bronchial respiration will be present, but in the former, vesicular breathing, feeble but distinct.

Vocal resonance is perhaps a little diminished, but it certainly is not as much diminished in intensity as is the respiratory murmur. It is usually diminished over the affected side as compared with the other side, but you must remember that this other side has been doing extra work, the lung contains more than the normal quantity of air, there has been exaggerated breathing on this side from the commencement of the effusion to its absorption, and it still continues to a certain degree during the adhesions, so that this lung is not as good a conductor of the vocal sounds as a normal lung or a lung that is doing only normal work.

Now, if you listen carefully you will notice that this feeble respiratory murmur is accompanied by a friction sound. As the roughened surfaces of the pleura come together and become more or less adherent, sounds are produced by their playing upon each other during inspiration and expiration, which are creaking in character, and have been called by some the new leather sound, or the parchment rubbing sound. Sometimes, however, there will be some pleuritic exudation which will give rise to a creaking, or rather a crepitating friction sound, so that it is possible to have a crepitant friction sound during the period of absorption, though, as a rule, it is heard only during the period of fibrous exudation.

Differential Diagnosis.—Now, gentlemen, it hardly seems necessary to say that this disease can rarely be confounded with other pulmonary diseases, but

mistakes are made in its diagnosis, and the more I see of pleurisy the more I feel that physicians do not fully appreciate the physical signs by which it may be recognized. I see it go very often unrecognized; that is, I find it confounded with something else, or I find its existence in connection with some other disease unrecognized.

Sero-fibrinous pleurisy may be confounded with *pneumonic* or *phthisical consolidation of the lung;* it may be confounded with *upward enlargement of the right lobe of the liver;* it may be confounded with *cancer*, or *with any tumor developed within the pleural cavity.* It is possible to confound *it with consolidated lung, not pneumonic, but associated with an aneurismal development* so as to press upon the main bronchus of the left side; that condition of the lung which sometimes results from pressure upon the bronchus by an aneurism of the descending portion of the arch of the aorta, the aneurism enlarging backward so as to press upon the left bronchus. Such a coudition is very likely to be mistaken for pleurisy with effusion.

Pleurisy of this variety is distinguished from pneumonia or phthisical development, in the first place, by the history of the two latter affections. Pneumonia and phthisis have a distinct history, and in these two affections there is an expectoration which is not present in pleurisy. I am now speaking of uncomplicated pleurisy; then, by the expectoration and by the general appearance of the patient you will be enabled to make the differential diagnosis between sero-fibrinous pleurisy on the one hand, and pneumonia and phthisis on the other. Then, pneumonia is ushered in by distinct symptoms which I shall speak of by and by, and phthisis has a history of phthisical development commencing at the apex of the lung. If you are still in doubt regarding the diagnosis, turn to the physical signs.

(To be continued.)

The Ambulance System in Paris. — Dr. Henry Nachtel, the originator of the night medical service in this city, read a paper before the Paris Academy of Medicine, November 30th, on the "Ambulance System of New York." He praised very highly the efficiency of this system, and contrasted it with that which now exists in Paris. In that city the method of getting emergency cases into the hospital seems to be of the most primitive kind. When a wounded or ailing man is found, policemen take charge of the person, and he is carried to the nearest apothecary. Though police stations abound in Paris, a person suffering from an accident is never carried there. A litter has to be hunted up, and then porters found, who transport the persou either to his house or to the hospital. Before all this can be accomplished, minor accidents, for want of immediate attention, become of the most serious character. Dr. Nachtel thinks even that deaths frequently occur in Paris from want of celerity in the transporting of patients. In dwelling in a most thorough way on the many advantages of the New York ambulance system, Dr. Nachtel expressed the hope that the New York system might be adopted in Paris. A commission, composed of MM. Larry, Legouest, Vulpian, and Chereau, was appointed by the Académie de Médecine to study the whole subject.

A New Small-Pox Hospital.—A survey of North Brothers Island has been made by the City Board of Health with a view to ascertaining its availability for a small-pox hospital.

Original Communications.

CHLORAL HYDRATE.

By H. H. KANE, M.D.,

NEW YORK.

CHLORAL IN SIMPLE INSOMNIA AND THE INSOMNIA OF DELIRIUM TREMENS AND INSANITY.

Chloral hydrate is the typical hypnotic. Above all its other actions stands forth its power to produce sleep, both in health and disease. In the study of its use in insomnia some heed must be paid to the different forms of this affection, to not all of which is it equally suited.

Prof. James Sawyer,[1] of Queen's College, divides insomnia into three groups which he names "psychic," "toxic," and "senile." The psychic form may be due to sudden and severe mental shock, which will sometimes at once induce persistent insomnia; or to prolonged mental strain, in all its varied phases, which produce partial or complete vaso-motor paralysis of the intracranial blood-vessels. The subjects of this form of insomnia are mostly men, particularly those of nervous temperament. A well-marked group of symptoms always follows prolonged suffering from this affection, most of which are given by certain writers among the signs of cerebral hyperæmia. It is probable that they mark what may be called irritable exhaustion of the brain, attended by more or less abnormal increase of intracranial vascularity, and accompanied by some general prostration of the bodily powers. In this form, an unnatural excitation of the cerebral vessels is the initial fault. In the next, the toxic form, a poisonous agent maintains cerebral vascularity at such a height that cerebral activity—that is, wakefulness—is an inevitable consequence. Such a poison may be introduced into the body from without, or it may be a product of diseased processes arising within the body itself. The external poisons which most frequently give rise to sleeplessness are tobacco, alcohol, tea, and coffee; the internal products which accumulate in gouty persons and in subjects of kidney d sease. When due to the latter cause (internal poisons), the insomnia is rarely complete, the patient complaining that he has great difficulty in falling asleep, that he is easily awakened, and that he always dreams when asleep. The senile form is due to degenerations of the smaller cerebral arteries; the vessels become less elastic, and physically unable to adapt themselves to the condition of relative arterial anæmia which is requisite for healthy sleep. In the treatment, soporifics are often necessary Of these, the chief are chloral, opium, morphia, the bromides, Indian hemp, alcohol, and affusion with cold water. In the severer forms of psychic insomnia, sleep must be at once procured by some efficient hypnotic, preferably chloral. In the more chronic forms, chloral should be sparingly used. In the well-nourished, bromide of potassium, in from thirty- to sixty-grain doses, is by far the best hypnotic. Tincture of ergot or tincture of digitalis may be combined with it. In many cases of chronic psychic insomnia, when the patient is worried, sorrowful, weakly, and anæmic, alcohol, in the shape of a "night-cap," is without an equal. The formation of regular habits and the taking of sufficient daily exercise should be

[1] (Lancet.) Braithwaite's Epitome, Mar., 1880.

insisted upon. In the toxic forms the external poisons should be removed; the treatment of the internal form involves the treatment of the diseases from which the poisons are derived. Senile insomnia is very obstinate; perhaps in the bromides, with full doses of hop or henbane, we have the best and least harmful means for its relief.

Chloral is especially suited to the sleeplessness of children, as first pointed out by Liebreich and Bouchut.[2] As has been already said, they bear proportionately larger doses than adults.

Dr. M. M. Palten, in the *St. Louis Med. and Surg. Journal*,[3] highly commends it in from four- to twelve-grain doses in syr. tolut., in the night terrors of children, which, if allowed to continue, may, he thinks, lead to the production of epilepsy.

Dr. E. P. Hurd,[4] of Newburyport, Mass., writes that he has found chloral especially efficacious in the insomnia of childhood. Stokoe[5] also endorses it for this purpose. I have myself used it largely in overcoming the fretfulness of infants and children, and have found it to produce a quiet, natural sleep, and to be free from the danger attending the use of opium. In children, as in adults, the effects of a single dose at bedtime sometimes seems to "hold over," giving quiet rest for several nights in succession. I am by no means in favor of constantly dosing children with strong drugs intended to produce sleep, but there are cases in which a quieting medicine may avert positive disease as yet undeveloped, and to such cases this drug seems especially suited.

The literature of this subject is filled with testimony regarding the value of chloral as an hypnotic. Its action is, as a rule, uniform, when given in cases to which it is suited. Thus Dr. J. Hughes Bennett[6] used it in twenty-one cases of consumption, making seventy-seven observations. With but two exceptions deep and healthy sleep was produced, by from twenty- to thirty-grain doses. In one case thirty grains produced an excited state approaching delirium, for some hours. In one case it caused vomiting twice when taken with cod-liver oil. When taken alone there was no vomiting. The relief to cough was great, and neither head troubles nor digestive disturbance were seen, such as is the case when opium has been taken.

In some cases it certainly does produce headache and digestive disturbance, but these are the exceptions to the rule.

As sleeplessness is usually a symptom of nervous disease, and as patients of this class are prone to form the so-called chloral, opium, or morphine habits, great care should be exercised in using the drug. A prescription which allows the patient to get the drug and use it at his pleasure should never be given. Where possible, the physician should give it himself when necessary, and the patients should be kept from a knowledge of what they are taking.

While being the typical hypnotic in simple insomnia, chloral hydrate does not act so well in cases when the sleeplessness is caused by pain. In such cases the formula advised by Bartholow[7] is excellent. He says:

"Chloral does not exert any chemical action on atropia when the two are held in solution together—for dilatation of the pupil of a cat takes place when the combined solution is instilled into the eye. Dilatation of the pupil also takes place when they are administered hypodermically together.

"An apparent antagonism is observed, as regards their action on the heart, when the solutions of chloral and atropia are placed in contact with the heart of a frog, when in position in the chest after division of the medulla, or when the heart is removed. The action of the heart is further found to continue much longer when a lethal dose of chloral is administered together with atropia. In rabbits the same result is produced by the conjoined administration of the two agents.

"Atropia is found to prolong the chloral narcosis several hours in rabbits, and diminishes the sensibility to pain.

"In man the excitant action of atropia hinders the occurrence of the chloral narcosis, but rather deepens the sopor, when it at last supervenes. The effects of atropia last much longer and are apparently in no way prevented by chloral.

"Morphia deepens in every way the effects of chloral. The author of the paper found, in the course of some experiments on himself, that many of the unpleasant effects of morphia are modified, as regards the wakefulness caused by the latter, but are not modified as regards the subsequent nausea, vomiting, headache, vertigo, and constipation. When the two agents are administered conjointly, a much less quantity of chloral is necessary in order to produce sleep.

"These agents act much more favorably when administered simultaneously. Chloral causes sleep, morphia relieves pain, atropia prevents or lessens the depression in the respiration and cardiac movements caused by the other two, while it contributes to their cerebral effects.

"These physiological studies are confirmed by the therapeutical results. The combination of chloral, morphia, and atropia is adapted to those cases of *insomnia* caused by pain, or in which chloral or morphia alone merely increases the cerebral excitement—as in hypochondria, puerperal mania, etc. This combination is also indicated in cases of fatty and irritable heart. When *pain* is to be relieved, chloral is not so serviceable as the combination with morphia and atropia. The local administration—that is, the insertion of the medicament at the site of pain—is more effective than the merely systemic impression. This is especially the case in tic douloureux, sciatica, and coccydynia, which are much more effectively treated by injections made in the neighborhood of nerves, the seat of pain. The combination of a local irritant and benumbing agent with a systemic anodyne is more curative than either used singly.

"In cases of *muscular spasm*, the author of the paper had obtained excellent results from the combined use of chloral, morphia, and atropia, and he especially called attention to the efficacy of these agents in the *cramps* of *cholera*. Many cases of *spasmodic asthma*, *hay fever*, etc., have been benefited by their conjoint administration."

Demarquay[8] advises great caution in the use of this drug as an hypnotic in old or greatly enfeebled people. Ogle[9] has had good results with it in senile insomnia.

The following curious episode is of interest:

The *Gazette Medicale de Bordeaux*[10] states that a dis-

tinguished veterinarian of that town communicated to the medical society the fact that several coachmen had been in the habit, for some time past, of giving chloral to horses under their care, in order to render them less spirited and more easy to drive. The plan answered its end admirably, for very fiery horses, which could hardly formerly be kept in hand, became, after a few days of this calming regimen, quite gentle and quiet. However well this suited the coachmen, their masters were not a little surprised at the change, and one of them employed a veterinary surgeon to ascertain the cause of this great change. He found the animals exhibiting a tendency to sleep, but failed to discover the cause of this, until one day by accident he found a bottle half full of a solution of chloral. The coachman confessed to having administered a portion of this every morning, and it seems to have become the custom of the degenerate jehus of the neighborhood to follow the same practice.

Dr. Benjamin Lee,[11] of Philadelphia, has twice, in the same case, tided the patient past the time for a chill, by putting her fully under the influence of chloral, she being and remaining fast asleep at the time of the expected attack. Dr. T. W. Grimshaw,[12] of Dublin, having found it possible to convey a very sick patient a distance of sixteen miles in a carriage by means of two ten-grain doses of chloral, suggests its employment in time of war to facilitate the removal of the wounded when it is necessary to carry them long distances.

There are two diseases wherein prolonged insomnia is often the most prominent symptom, and that which chiefly endangers life. The use of chloral hydrate in the treatment of these affections (delirium tremens and insanity) requires a somewhat extended consideration.

In delirium tremens this drug has been often used sometimes with good, at others with bad results, due to the fact that in many instances a regular routine treatment is pursued without any reference whatever to the state in which the patient is found. In those cases where the patient is utterly exhausted and in an anæmic condition, with weakened heart-action, stimulants, capsicum, digitalis, and quiet are called for. When the patient is noisy, with flushed face, reddened conjunctiva, and strong cardiac action, a good purgative, followed by one or two doses of chloral, will produce the much-needed sleep, and in many instances save the patient's life. In still other cases, where there seems to be danger of apoplexy, a good bleeding, followed by a single dose of chloral, say thirty grains, by the rectum, will work marvellously. Such a case is related by Dr. R. F. Lewis, of Lumberton, N. C., as follows:

"A young man of this town, six months ago had a severe attack of *mania a potû* which lasted nearly two weeks. About a month ago he began spreeing again, and drank quantities of spirits. He had not slept for three days and nights when I was called to see him. I succeeded in getting him to undress and go to bed, when I gave him thirty grains of chloral. It seemed to rather increase his delirium. At the end of an hour I repeated the dose. There was still no inclination for sleep, and it required all my persuasive powers to keep him in bed. I found his pulse strong, hard, and very frequent, and I thought that if ever a man needed bleeding this one did. Acting upon this belief I corded the arm and abstracted about sixteen ounces of blood. Before I could properly dress the wound he dropped into a quiet slumber and remained so for seven hours, when I easily aroused him and gave him some soup, which he drank, and soon was again asleep, which continued for five hours longer, when he awoke, expressed himself as all right, got up, dressed, and ate breakfast, and thus his spree was ended and his threatened *mania a potû* aborted.

"It has fallen to my lot to treat a good many cases of alcoholism. I have used chloral freely with them, and with never anything but the happiest effects. I have often been called upon to help an old gentleman out of a debauch, and he has frequently said to me that it was the next best thing to whiskey."

In a clinical lecture recently delivered at the Royal Infirmary, Edinburgh, Dr. Balfour[13] discussed the history of the treatment of delirium tremens. Up to a comparatively recent period the production of sleep was regarded as the one object of treatment, and this led to the unjustifiable use of narcotics. Subsequently the expectant plan was pursued, on the belief that the disease was self-limited and would terminate naturally in from sixty to seventy-two hours. More recently still, modern chemical research having supplied us with safer and more active nervine sedatives, the production of sleep has again been recognized, not as a *sine qua non* in the sense of the former dogma that the patient must sleep or die, but a very important and most efficacious means of cutting short the attack—so safe and efficacious, in fact, that it seems almost a premium on vice to promulgate it, though it is neither safe nor efficacious, unless properly employed. The digitalis treatment, half a fluid ounce at a dose, has never been employed at the Royal Infirmary, as is also the case with the cayenne pepper method, scruple boluses every two or three hours, although each of these plans has its advocates. The tartar-emetic treatment, in full emetic doses, is more useful in cutting short a debauch than in treating delirium tremens, although it may prove a valuable adjunct in the latter condition. Chloroform is too dangerous, and not sufficiently reliable as a remedy.

Dr. Balfour then discusses bromide of potassium and chloral hydratis, the latter of which being the remedy on which he relies. He closes his lecture with the following summary: "I have long been in the habit of treating cases of delirium tremens by giving forty grains of chloral hydrate every hour, for three times if necessary. Sometimes, but rarely, the first dose has been enough; most commonly two doses have been required, and it is only in the rarest instances that the third dose has been necessary. If the attack be ushered in by *status epilepticus*, I shorten the interval between the doses to half an hour. Should the heart be feeble, I give each dose of chloral in half an ounce of the infusion of digitalis; the chloral, unlike the bromide, has no tendency to weaken the heart's action, while, like chloroform, it seems to induce a more equable distribution of the blood, the digitalis toning the heart and increasing the arterial blood-pressure. Even though pneumonia be present, though the risk to the patient is enormously increased, the treatment does not require to be in any way modified; it is still of the utmost importance to quiet the nervous system and keep up the heart's power.

"So far, therefore, as our present experience is concerned, we seem to possess in hydrate of chloral a remedy which in all such cases, from the slightest

[11] Medical Brief, October, 1876.
[12] Practitioner, 1871, p. 62.
[13] Braithwaite's Epitome, March, 1880.

to the most severe, acts rapidly, safely, and efficaciously—*cito, tuto et jucunde*—and which seems to deprive indulgence in drink of all its horrors and nearly all its dangers. Unquestionably, fatal cases must sometimes occur under this as well as under other modes of treatment, but the number of them must be much decreased, because, from the rapidity with which a cure is brought about, many dangerous risks are averted. Thus we avoid all the risks arising from a long continuance of maniacal excitement, or from a suicidal state of mind, all risk from the exhaustion following persistent sleeplessness or defective nutrition, the result of long-continued insufficiency of food, etc."

Risks are not from treatment, but from previous state of health. If he have fatty heart, is an epileptic, or is exhausted by continued debauchery, he may die suddenly.

Dr. Wm. J. Wilson,[14] Assistant Surgeon, U.S.A., Fort Niagara, Youngstown, N. Y., finds that *when the pupils are dilated*, chloral does not produce a calmative, but an opposite effect.

The following excellent summary of the treatment of this disease is made by Dr. Austin Flint,[15] of this city:

"Opium, given in large and enormous doses, as was formerly the practice, was conclusively shown by Ware to be pernicious. Sleep is the desired object, but narcosis is not a substitute therefor. It is hazardous to induce the latter. But an opiate, in small or moderate doses, is often useful. A quarter of a grain of the sulphate of morphia every four or six hours, or an equivalent of codeia or some other preparation, is the safe limitation as regards dose and intervals. Alcohol is relied upon by many, but opposed by some on the ground of moral considerations. The latter are of little weight. The patient will not be likely to resume the habit which has caused the disease any the more because alcohol may have conduced to the recovery. In the treatment alcohol should be given in moderate quantity, and suspended when sleep occurs. It is indicated especially when the patient is much enfeebled, and the pulse denotes cardiac weakness. The inhalation of chloroform may be tried, especially when the delusions induce extreme terror or violence of delirium. It sometimes is useful, but more frequently it fails. The attempt to produce anæsthesia is often resisted by the patient, and the violence of the delirium is thereby increased. The hydrate of chloral is more easily employed. It sometimes acts like a charm. Proper precautions are to be observed in the use of this remedy. The bromides may be given with much less reserve. They should be fairly tried. Their effect is sometimes excellent and sometimes *nil*. Digitalis is in some cases notably efficacious; it is indicated especially when the heart's action is frequent and weak. It is unnecessary to give this remedy in doses of from half an ounce to an ounce of the tincture, as may be done with safety; half an ounce of the infusion every two or three hours will secure all the benefit to be obtained from it. Antimony is suited to a certain class of cases, namely, those in which the symptoms are violent, and the patient robust, and the action of the heart strong."

Two cases of death in this disease from small doses of the drug are related by Dr. Frantz,[16] and a number from larger doses can be found in my articles on "Poisoning and Death." In one of Dr. Frantz's cases the dose of twenty grains was given one night and repeated the next night. The patient slept all night, awoke in the morning, fell into a state of collapse, and died in a few hours. In the other case two doses of twenty grains each were given. Quiet sleep all night. In the morning, respiratory embarrassment, collapse, and death in an hour's time. At the autopsy of the first case some hypostatic congestion of the left lung was found, as also intense cerebral congestion. In the second case all the organs were found in a normal condition.

Dr. Frantz ascribes the death to syncope, due to sudden paralysis of the cardiac muscles. Alcoholic subjects, according to him, present unfavorable conditions of nutrition, a special dyscrasia, and gastro-intestinal catarrh of more or less gravity. In these conditions he thinks it advisable never to give more than from thirty to forty grains of chloral at one time. This dose he considers safe, looking upon the above-recorded cases as entirely exceptional.

Naphey[17] says: "It has been shown, beyond reasonable doubt, by Dr. Madison Marsh, of Louisiana, and later by Dr. Ernest Magnan, of Paris, that drunkards do not bear chloral at all well. Its use by them, even in moderate doses, is liable to be followed by sudden death."

A case somewhat similar to those related by Dr. Frantz, although the patient did not die, is related by Dr. R. L. Pinching,[18] of San Francisco, Cal.

"In one case in which a medical friend called me to see a patient laboring under this disease, he had administered thirty-grain doses every hour for several times. The effect of these doses was to produce great prostration, feebleness of the pulsations of the heart, simulating mercurial erythismus, syncope, and all the appearance of speedy dissolution, from which he was only saved by a discontinuance of the chloral and the free administration of brandy, quinine, and nourishment."

Dr. Geo. W. Holmes, of this city, writes me that he has used chloral with success in this disease, save in one case, where it interfered with the pulse and respiration. The drug was stopped and stimulants given, with the result of relieving all bad symptoms.

Dr. R. Köhler's report on "The More Important Events in Prof. Bardeleben's Clinic at Berlin in 1876" (*Charité-Annalen*, 1878)[19] states among other things that in the treatment of delirium tremens chloral has been replaced by morphia, more than half the cases having died of late years under the chloral treatment. With the reinstatement of morphia the mortality appears—and Prof. Küster has made the same observation—to have again diminished.

In the discussion of a case of delirium tremens reported to the St. Louis Med. Society by Dr. C. Hughes of that city, Dr. C. E. Briggs[20] said that the occurrence of a number of sudden deaths during the treatment of this disease by chloral, notably one in an institution near by, had deterred him from using it. He prefers minute doses of antimony and morphia. Dr. Hughes' case reads as follows:

"The value of chloral hydrate enemata may be discerned from the following memoranda of a persistently recurring case of delirium tremens:

"Antoine F—— had the first attack to which my attention was called on the 22d of May, from which he was convalescent by the 31st inst. Nothing could

be tolerated by the stomach. Chloral hydrate enemata, in sixty-grain doses, with beef-tea, promptly resulted in sleep each day.

"On the 6th of June following he was again attacked, having also two epileptic seizures; the general cerebral condition was one of congestion. The same process as before was repeated with success. From August 23d to August 30th he had a recurrence of the disorder, and the same treatment was repeated with a like result. The quantity of the injections in these instances, however, being eighty grains of chloral hydrate. The next attack was on the 20th of September and ceased on the 27th. He was again down on the 1st of October, remaining sick until the 15th. On the 23d of February, 1878, he had another attack, which lasted to the 1st of March. On the 21st of March he had another attack, which continued to the 27th. From April 19th to the 26th he again had delirium tremens, and on July 1st, 2d, and 3d following he fell sick and died of exhaustion, without delirium.

"During the intervals between his attacks, the patient took, though irregularly, bromide of ammonium, elixir of the valerianate of ammonia and camphorated tincture of opium, as a stimulant, and bromide of calcium and the syrup of the lactophosphate of calcium as a brain nutrient and tonic."

Dr. Lutz said that he found the sleep that followed opium much more satisfactory and refreshing than that which followed the use of chloral, and that in some instances the patients awoke from the chloral sleep as delirious as before it was given.

Dr. G. M. B. Maughs did not believe at all in the use of such powerful drugs in this disease. He believed that it often quieted by killing.

Dr. Hughes said, in answer to Dr. Maughs, that in therapeutics, as in surgery, success depends very materially on the way in which one uses his tools. He could say, without exaggeration, that he had in his professional experience, in the hospital at Fulton and elsewhere, administered several hundred pounds of chloral hydrate; not mainly, however, to delirium tremens cases, but largely to cases in which there was delirium and insomnia; and yet he never knew of a sudden death resulting from it. In his practice he never administered two successive doses of chloral of sixty grains or more after an interval of less than six hours, and seldom had he administered that quantity more than once in twenty-four hours. The successful administration of chloral hydrate depends upon the manner in which it is used, and the deleterious consequences depend on the injudicious employment of the drug. It is more dangerous in small quantities, *e.g.*, ten or fifteen grains, often and continuously repeated over a lengthened period, than in large doses—forty to sixty grains—with a long interval between them. Doses of any remedy which are abortive in their effects are unsatisfactory and often unsafe. That chloral hydrate in small doses is intoxicating there is no doubt. It is much like chloroform, alcohol, and opium in this regard. Full doses induce sleep, small ones intoxicate. But there was not a case on record—and he challenged the proof—where a single forty-grain dose of chloral hydrate, given to a recumbent patient who had not been previously taking it to saturation in small doses, had produced fatal consequences. Patients who had died from chloroform had died from having the blood surcharged with the poison by too oft administration of too small doses. Certainly chloral is dangerous, so is opium, so is almost every potent drug, so is the assassin's knife, but the surgeon transforms it into an implement of cure. If the dead could speak they would probably tell us that opium had slain more victims than delirium tremens. He did not advocate chloral in preference to all other drugs at all times and under all circumstances as an hypnotic in delirium tremens; never to the exclusion of the bromide of potassium and other efficient remedies, especially nutrients and capsicum. In the vast majority of cases of delirium tremens the system would right itself without narcotics if the stomach will but retain food. He believed he had cured as many cases with beef-tea and capsicum as with anything else, and without any other remedy, except to let nature, a quiet room, and time restore the shattered nervous system. Chloral, if used at all, must be used in such doses as will take possession of the nervous system and when the patient is in a recumbent position, and not so frequently repeated either in small or large doses as to saturate the blood and poison the patient beyond therapeutic necessity.

Some authors and many practitioners, taking the general rendering of the statistics of Näcke of Dresden as their groundwork, refuse to use chloral on the hypothesis that as the kidneys are diseased in eighty per cent. of these cases, the danger lies in the fact that the drug is not properly eliminated. This is an error, and I must confess to having mistook the author's meaning myself. He says [21] that "in eighty-two per cent. of the cases, there was *temporary* albuminuria (*renal and cardiac affections excepted*). His treatment is by full doses of chloral (fifty to eighty grains in two doses), but his percentage of mortality (twenty-four per cent.) is not encouraging. He says further: [22]

The female sex is less exposed to delirium tremens than the male among the working classes; persons who are exposed to the vicissitudes of the weather, or who have much to do with spirits, *e. g.*, innkeepers, waiters, etc., are more liable to contract it. It occurs most frequently in individuals between thirty and fifty years of age, especially between thirty-five and forty. The youngest patient was eighteen years old. The greater number of cases have come under notice late in the latter part of autumn and in summer. In five per cent. of the cases the affection is merely an abortive form of the disease; it might perhaps be regarded as a delirium tremens which has not gone beyond the prodromal stage. This slight form frequently, at a later period, develops into the genuine delirium tremens. In the female sex this abortive form is met with, as a rule, and the real delirium tremens only in very exceptional cases. Another form of the affection, which is little known and very seldom met with, is the chronic delirium tremens. The author gives this name to a series of abortive paroxysms, which are preceded by an acute, well-defined attack of delirium tremens. There are generally more or less lucid intervals between the attacks. This condition lasts for weeks or even months, and the prognosis is very bad. The prodromal state generally extends over two to three days. The characteristic symptoms of delirium tremens are, among others, great thirst, an increased secretion of sweat, and more or less acute digestive troubles. In one-third of the cases there was a slight febrile movement; the temperature, however, did not go beyond 100.6°. A high temperature would be a symptom of some in-

[21] Phila. Med. and Surg. Reporter, Sept. 27, 1879.
[22] London Medical Record; North Carolina Med. Journal, Sept., 1879.

ternal inflammatory process. The febrile movement does not occur during the prodromal stage, and as a rule only on the first day of the actual delirium. The author explains it as a mere rising of the physiological exacerbation of temperature which occurs at night. The pulse and respiration were normal. In eighty-two per cent. of the cases there was albuminuria (renal and cardiac affections excepted). In one-fourth of these cases this transitory albuminuria was complicated with fever. The albumen increased in proportion as the temperature rose; but not in proportion with the delirium. It generally vanished as soon as the paroxysms were over. It appears from some chemical tests that an exceedingly small amount of phosphates is excreted at first, and that it gradually increases during the course of delirium tremens. The hallucinations are mostly illusions of sight and hearing; occasionally the taste and tactile perception are also affected. The patient is in a state of profound depression; he is surrounded by phantoms which persecute him. In one-third of the cases the patients had visions of animals, and contrary to the usual assertion, they saw large animals, not merely small ones. The visions vary very often, so does the patient's state of mind. All the symptoms of the affections exacerbate at night; even after a good night's rest they are apt to recur. The death-rate from delirium tremens varies very much. The first paroxysm is, as a rule, the most dangerous one. In no case has the *post-mortem* examination revealed any peculiar changes in the body. Narcotics, if given at the onset of the affections in moderate doses, seem to shorten its duration, and to render it less violent. Three to five grammes of chloral, given in two doses, generally induced sleep; the dose had often to be repeated. Straight-jackets, straps, etc., ought never to be used, as they are apt to produce hallucinations. In cases where the patient is likely to be very violent, the author advises that he should be shut up in a warm padded room by himself, and be dressed in untearable garments.

It has been used successfully, and has been highly spoken of in this affection by Drs. Albert Day,[23] Orlow,[24] A. P. Hayne,[25] Home of Inebriate, San Francisco, Cal.; Langenbeck,[26] D. H. Kitchen,[27] Blood,[28] Rigden, and Reynolds,[29] J. H. Barnes,[30] Rancurel,[31] Abeille,[32] Curschmann,[33] P. F. Harvey,[34] J. M. Keniston,[35] Butler Asylum, Providence, R. I.; Chas. W. Earle,[36] Washington Home, Chicago, Ill.; Atkinson,[37] Carl Bernard,[38] Barnes,[39] Chapman,[40] Richardson,[41] Barclay,[42] A. S. Payne,[43] Siredey,[44] and J. W. Hickman.[45] The following gentlemen write me that they have used the drug with much satisfaction and without accident in this disease: A. R. Kilpatric, Navasota, Texas; J. G. OPIUM NARCOSIS IN AN INFANT SIX WEEKS OLD.

RECOVERY UNDER THE USE OF BELLADONNA.

BY S. C. CHEW, M.D.,

PROFESSOR OF MATERIA MEDICA AND CLINICAL MEDICINE IN THE UNIVERSITY OF MARYLAND, BALTIMORE.

THE following case is reported because it is deemed a valuable contribution, as it is perhaps the most recent one, to the history of "Physiological Antagonism between Medicines," to which attention has been called by the able lectures of Prof. Barthelow in the MEDICAL RECORD. It is of special interest in view of the age of the subject, and the peculiar susceptibility to narcotism from opium in early infancy, as well as the fact that six hours elapsed from the ingestion of the poison to the first institution of treatment, and the further fact that recovery seemed clearly attributable to the antagonistic method of treatment employed.

On returning to my office at half past six o'clock in the evening of November 30, 1880, I found an urgent message to visit the child of Mrs. X——, which was just six weeks and two days old.

I was informed on reaching the house that some powders containing one-fourth of a grain each of sulphate of morphia, previously directed for another member of the family, had by mistake been substituted for a package of pepsin powders that had been ordered for the baby. One of these morphia powders had been administered to the child at half-past twelve o'clock, or just six hours previously to my visit; and I was told that the whole amount contained in the powder was certainly given, the particles adhering to the spoon being carefully wiped out with the finger and placed in the child's mouth in the belief that it was pepsin. I afterward had the powders carefully weighed and found that four of them weighed just one grain.

It is to be noted, however, that immediately after swallowing the powder the child took its nursing bottle of milk, a part of which was regurgitated from the stomach after the fashion of babies. Whether any of the poison was in this way ejected or not, cannot positively be stated; but certain it is

that enough was retained to produce the profound narcosis in which I found the child.

When the sleep had lasted for some hours, alarm was taken from the difficulty in arousing the infant; but apart from a few attempts to awaken it, after each of which it would instantly relapse into deep sopor, nothing was done from the time when the morphia was administered until the hour of my visit. The pupils were then contracted to pin points, the respiration was exceedingly feeble and shallow, and the pulse at the wrist scarcely perceptible. The use of an emetic or the stomach-pump was obviously out of the question, as in the time which had elapsed since the drug was given, it must have been completely diffused throughout the system.

The only measures available were such as would physiologically antagonize the morphia by maintaining the circulation and respiration. I accordingly directed some strong coffee, which was ready in the house, to be given in teaspoonful doses every few minutes, while I went to my office in the neighborhood for some tincture of belladonna which I knew to be reliable, thinking that this might be more manageable than atropia in so young an infant. On returning I gave a drop and a half of the tincture in a little water, repeating half a drop every twenty or thirty minutes. At the same time I endeavored to arouse respiration by applying a cloth dipped in ice-water to the back of the neck for a moment at a time, with the effect of causing deep gasping inspirations. Gentle shaking and slight pricking with a pin were also occasionally resorted to; but all violent measures were avoided as being likely to exhaust the little strength that remained.

When four drops of the tincture of belladonna had been taken, a bright scarlet hue diffused itself over the face, arms, and gradually over the entire body of the child, upon which the interval between the doses was extended to an hour. Synchronously with the redness of the skin other evidences of the physiological action of belladonna were apparent; the pupil began to expand, the pulse became quicker and stronger, and the respiratory acts distinctly deeper and more frequent. So prompt indeed was the response of the respiratory function in some measure to the belladonna influence, that it did not seem necessary to use the faradic battery which I had made ready.

In withholding it I was borne out by the observation of Dr. Johnson, of Shanghai, quoted by Professor Bartholow in his second Cartwright lecture, to the effect that when the influence of belladonna has once begun, provided respiration be tranquil and regular, however slow it may be, it is injurious to resort to artificial respiration.

By half past eleven o'clock, six hours after I first saw the child, its respiration and circulation were so completely re-established, and it was so easily kept awake, that I considered its condition perfectly safe, and left it, directing, however, that it should be awakened every hour, so as to test the remanent degree of narcotism, and that if there should be difficulty in waking it, I should be notified. On the following morning it was perfectly well.

Now, in this case, as suggested by Professor Bartholow in reference to some of those which he recounts, it may be necessary to estimate the part performed by other agencies, as the coffee, the shaking, and the shock of cold to the spine. But yet the improvement seemed to result so directly from the action of the physiological antidote that I have no hesitation in ascribing the child's recovery chiefly, or exclusively, to the belladonna, which met and antagonized the morphia at the three main points along its whole line of action, the pupil, the pulse, and the respiration.

The observation of Professor Bartholow, that the state of the pupil is, in such cases, not a safe guide, is, I am persuaded, a most important one, the truth of which has been too much neglected. If the belladonna or atropia be too boldly or carelessly administered, in the belief that until the pupil expands it may be given *ad libitum*, there is grave danger lest its own sedative influence be added to that of the opium. It should be used for a definite purpose, and that purpose is not to dilate the pupil, but to maintain the respiration and circulation, which must be effected by the stimulant influence of small doses.

In connection with this subject of antagonisms, I may remark that Professor Bartholow, in his fifth Cartwright lecture, states that at least six remedies have been used with success in tetanus, viz.: chloroform, chloral, tobacco, bromide of potassium, physostigma, and gelsemium. To this list must be added conium, or its alkaloid, conia, as employed by Professor Christopher Johnston in six cases of traumatic tetanus, two of which, by the kind courtesy of that gentleman, it was my privilege to witness. In three of these cases, two of which are reported in full, and with very interesting comments, in the *American Journal of the Medical Sciences* for July, 1870, the use of the conia was followed by recovery.

One other instance of the successful use of conia in tetanus is recorded by Dr. Corry in the *Dublin Quarterly Journal of Medicine* for November, 1860.

I desire especially to call attention to these results, from the fact that Professor Bartholow, in his able and widely read "Treatise on Therapeutics," remarks that "conia is certainly indicated in tetanus, hydrophobia, and strychnia-poisoning, but hitherto it has not succeeded, probably because inert preparations were employed." This statement, as regards tetanus, needs correction, as in four recorded cases of that disease conia has succeeded.

There cannot be a more prominent instance of physiological antagonism than that which exists between the state of the spinal cord in tetanus and that produced by the powerfully sedative action of conia. In tetanus death generally results from rigid contraction of the respiratory muscles; in conium-poisoning, from paralysis of these muscles. Whether the paralyzing action of the conia extends inwardly from the terminal filaments of the motor nerves to the cord, or, as maintained by Verigo, in the reverse direction, it is no doubt powerfully exercised upon the cord.

The recoveries obtained by Professor Johnston and Dr. Corry were the direct consequences of physiologically antagonistic medication.

Baltimore, Dec. 20, 1880.

Capacity for Study in Children.—Chadwick, the best authority (says the *Boston Medical and Surgical Journal*) on the above topic, concludes that a child from the age of five to seven can attend to one subject for fifteen minutes; from seven to ten years, about twenty minutes; from ten to twelve, about twenty-five minutes; from twelve to eighteen, about thirty minutes. The total daily mental work suitable for a young person from twelve to sixteen years of age, taking Chadwick's estimates as a basis, and making allowance for the rapid development in this period, is placed at from five to six hours.

Reports of Hospitals.

PENNSYLVANIA HOSPITAL, PHILADELPHIA.

CLINIC OF R. J. LEVIS, M.D.,

SURGEON TO THE PENNSYLVANIA AND JEFFERSON COLLEGE HOSPITALS.

RARE CASE OF ANEURISM OF THE ULNAR ARTERY, SIMULATING MALIGNANT DISEASE, APPARENTLY CURED BY LIGATION OF THE BRACHIAL ARTERY, WITH ANTISEPTIC PRECAUTIONS.

THE next case that I shall present to you is one of great importance from a diagnostic point of view. It has occupied the minds of our best surgeons for several days past. The patient, about forty years of age, by occupation a butcher, has been sent to us from Port Carbon in this state. He presents a tumor occupying the upper third of the right forearm anteriorly, rather more inclined toward the ulnar side. The history is that he had been kicked there by a hog a year ago, but the patient knows of no other injury, and indeed the history is of little value. The tumor is quite painful, and has attained its size only within the past three weeks. There is a diffused pulsation all over the tumor, especially distinct at the ulnar side, while at the wrist the pulse is slightly perceptible in the radial, but not at all in the ulnar artery. The circumference of the arm over the tumor is about twelve inches. There are three separate diagnoses possible, each of which has a sufficiency of symptoms in its favor, namely, an abscess bound down by the fascia receiving transmitted pulsation, a pulsating sarcoma, and an aneurism. The diagnosis of an abscess is favored by the fact of its rapid development, for we cannot attach any great importance to the history of the injury, it having occurred so long ago. Marked pain and heat as symptoms of acute abscess are also lacking, though a chronic abscess need not present these symptoms. While, therefore, I do not exclude the possibility of an abscess, I cannot believe in its probability, and do not undertake to explore the tumor by incision, but will base my treatment on the suppositions of aneurism or malignant disease. I therefore propose a comparatively harmless procedure, namely, ligation of the brachial artery, which, if my conclusions are correct, will cure the aneurism. Should it, however, prove to be a malignant growth, nothing short of amputation of the arm will be of avail; and the ligation of the brachial will not increase the danger. As far as surgical literature goes, we have little or no information of aneurisms below the bend of the elbow. In passing I wish to mention that the patient has an enchondroma of some ten inches in circumference, growing from the thorax over the cardiac region, which receives a curious tremor from the beat of the heart against the chest.

While the patient is being etherized, some remarks concerning the causation, symptoms, and treatment of aneurism may not be inappropriate. You must know that the term aneurism is applied to a dilatation of an artery, and may be caused by injury or by atheromatous or other changes causing a weakening of the arterial coats. If the aneurismal sac is made up principally of the dilated arterial wall, it is called a true aneurism; if, however, the artery is ruptured, and the blood escaping finally obtains a kind of sac-wall of condensed cellular tissue, it is called a false aneurism. The symptoms of aneurismal tumors are pulsation, murmur, and thrill, with the concomitant features of progressive enlargement, more or less pain, and a certain elasticity upon palpation. If the artery be compressed above the growth the tumor will become more flaccid and smaller; but if compression be applied to the arterial trunk below, the sac becomes distended and therefore is increased in size and hardness. It is frequently difficult to be sure that the tumor is an aneurism, because lamination of clot within the sac may make the pulsation and thrill very indistinct; again, solid tumors lying over an artery may present transmitted pulsation. The introduction of the needle of the hypodermic syringe or aspirator will often clear up the diagnosis by giving exit to blood. Malignant growths often occupy regions prone to aneurisms, and if very vascular may present marked pulsation and simulate aneurism. A remarkable case of this kind was treated in this hospital some years ago by Dr. Morton, who ligated the internal iliac artery for supposed gluteal aneurism. The subsequent history of the case showed the tumor to be a malignant growth, though at the time of operation the opinion that it was aneurism was held by numerous able surgeons. The ligation relieved many of the symptoms, and probably prolonged the patient's life by cutting off the blood-supply of the malignant tumor.

This same question of diagnosis arises in the case before us, and it is by no means easy to determine whether this patient has a true aneurism of the radial or ulnar artery, or malignant disease involving the upper extremity of one of the forearm bones. If it is the latter, it is probably a round-celled pulsatile osteo-sarcoma. The fact that spontaneous aneurism in this locality is exceedingly rare renders the second diagnosis plausible. The only form of aneurism in this vicinity that is, or at least was not infrequently seen, is the traumatic form produced by wounds of the brachial artery in cases of venesection. Mr. Holmes, however, has recorded a case of aneurism of the upper part of the ulnar artery, that was seen at the Middlesex Hospital, and others have probably been observed. In this case it would seem to be aneurism of the ulnar, for the radial pulse is distinct, while the ulnar is not; the pulsation and murmur are more marked on the ulnar side, and the position seems perhaps too low for the brachial. There is at the present time some redness of the skin, and considerable pain on motion. When the arm is raised and pressure made upon the brachial, so as to cut off the blood-current, the tumor seems to become more flaccid. There is no enlargement or pain in the axillary glands, as might be the case in malignant disease, though not necessarily, especially if the form be sarcoma. The patient's general health is good.

Taking all things into consideration, I am rather inclined to regard the case as an inflamed ulnar aneurism, though I am bound to admit that the opinion of some of my friends, who regard it as malignant disease, may be correct. It is also possible that it is a ruptured aneurism with the blood-contents extravasated in the surrounding tissues. The case was recently presented at the meeting of the Philadelphia Academy of Surgery, and gave rise to much discussion because of its doubtful character.

The treatment of aneurism of the extremities consists of ligation or compression of the artery, and of incision into the sac with ligation of both ends of the artery. The ligature, as usually applied, is placed

on the cardiac side of the tumor, and as the blood-current is thus cut off the sac becomes filled with a solid clot, and gradually contracts until it finally becomes fibrous tissue. The collateral circulation in the meantime keeps up the life of the distal portion of the limb. Compression, which may be digital or mechanical, complete or incomplete, acts in a similar manner. For internal aneurisms we prescribe iodide of potassium in large doses, restricted diet, and absolute rest. In some cases electrolysis may be beneficial, and I have in a few instances introduced horse-hair into large aneurisms, where other treatment seemed unavailing, with the hope of producing fibrinous deposit and cure. The results, however, have not been very encouraging.

What should be done for this patient before us? I purpose ligating the brachial artery, as I have previously stated. It will be proper treatment for aneurism; and if the tumor does not seem permanently benefited by the operation, but continues growing, I shall reverse my diagnosis and advise amputation before the malignant disease, as we must then regard it, makes further progress.

I reach the brachial artery by an incision about two inches in length, over and along the course of the vessel, near the middle of the arm, in the groove along the inner side of the biceps and coraco-brachial muscles. Here I expect to find the median nerve crossing the artery, which latter is accompanied by its venæ comites. We shall carry on the operation under a carbolized spray, projected by this well-constructed atomizer, which is portable, and allows of the spray being raised or lowered at pleasure. The strength of carbolic acid in the reservoir is one part to twenty of water, which is reduced to one in forty by the admixture of the steam; while the instruments to be used are immersed in a solution of one part to forty of water. By slightly flexing the forearm upon the arm, I bring out distinctly the groove along the biceps and coraco-brachial, while the median nerve is made to stand out like a tensely drawn cord. I make my incision, as previously indicated, through the skin and superficial fascia, as I am not in the habit of taking up the superficial fascia on a grooved director. I now carefully cut through the deep brachial fascia, and have reached the median nerve, which presents a white and glistening appearance, and can be seen distinctly, even from a distance. I now separate the connective tissue with the handle of the scalpel, open the sheath of the artery, and have here the vessel exposed. I free it from its accompanying veins, and slip my aneurism-needle, armed with a carbolized catgut ligature, under the artery. My colleagues examine whether I have taken up the artery alone, without other structures, and we verify it by seeing that a temporary constriction of the same stops the pulsation of the tumor. I now tighten the ligature, cut the ends off short, close the wound by means of a few stitches of wire suture, and cover the part with charpie saturated with carbolized oil, retained by a roller-bandage.

. . . . . .

We have before us the case in which I ligated the brachial artery at my clinic one week ago. The obscurity of the diagnosis has not as yet been cleared up. The wound is absolutely closed, having healed in this short space of time, and there are no signs of irritation. We designate this immediate union. The ligature will soften and be absorbed. The pulsation of the radial artery has returned, while we cannot make out the pulse in the ulnar nor in the tumor. The eccentric aneurismal heaving and the aneurismal thrill which existed before the ligation have disappeared, yet there is no perceptible diminution in the size of the tumor. It measures now, as before the operation, twelve inches. The shrinking is evidently not rapid, if there is any at all.

The patient who has been the subject of so much discussion is now ready to return to his home. The tumor has shrunk considerably since the ligation about two weeks ago, giving now a circumferential measurement of about nine inches, and the man is free from pain and relieved of mental distress. The conduct of the tumor after the operation seems to point to aneurism rather than malignant disease, for although shrinkage did not occur rapidly, it was considerable, and I think more than would have taken place after ligation of the main trunk supplying a vascular sarcoma. Hence, I still believe it to be an aneurism bound down by the deep fascia, which has been cured by ligation of the brachial, and which will probably continue to shrink. I shall, however, endeavor to keep acquainted with the subsequent history of our patient.

TREPHINING FOR THE RELIEF OF TRAUMATIC EPILEPSY.

Thirteen years ago this patient sustained a comminuted fracture of the skull. At that time his physician elevated the fragments, and the man did well for three years. Afterward he habituated himself to the use of alcoholic stimulants, and for the past ten years has been a drunkard as well as an epileptic. At present he is weak-minded—indeed, almost an imbecile, and has an epileptic seizure every few hours. He is unfit for the purposes of life, and, in his present condition, is unhappy and a burden to himself and society. Bromide of potassium has some beneficial influence over his attacks, but the epilepsy has been increasing in severity, and the mental impairment becoming more marked.

At about the centre of the left parietal bone I find a hollow or depression, which clearly indicates the position of the fracture. The depression is irregular in outline, with an average diameter of two inches. The scalp-wound has left star-like cicatricial marks, and we suppose that a cranial depression exists in the course of one of these radiations.

At a consultation with my colleagues it was agreed to use the trephine as an exploratory measure, and I believe that we will thereby be enabled to find out the cause of the irritation, which probably consists of the pressure of the edges around the removed bone.

As a preparatory measure, the corresponding portion of the scalp has been shaven. The patient is now being put under the influence of ether, and I shall wait until complete relaxation has taken place. The muscles during the stage of excitement are tense, and keep the blood-vessels turgid.

A crucial incision is generally recommended, but I prefer a curved incision, which gives me a trap-door flap. It is immaterial how large a flap is made, and I therefore fully include the part. I am very careful, because in some regions there is but a dense membrane between my knife and the brain-substance. I have removed here the pericranium with the flap, which leaves the bone bare. A small cylindrical trephine will fully answer my purpose, while a conical instrument is preferred by those whose experience in this operation is limited, and who therefore feel safer with it. I fasten the centre-pin, and allow it to remain in position, until by a few semicircular turns I have made a groove. I now retract the

centre-pin, and cautiously continue the rotatory movements, stopping occasionally to remove the particles of bone from the groove with a toothpick, which at the same time answers the purpose of a probe to ascertain whether the cranium, which is thicker in some regions than in others, has been penetrated at any point. We become conscious that we have penetrated the cranium by a want of resistance, or by a feeling which can be acquired only by experience.

Having now removed a disk of the skull, I can do no harm by carefully passing this elevator underneath the skull to detect a projecting fragment of bone or an exostosis, but am unable to find anything. This will, therefore, conclude our interference to-day, as I do not desire to set up cerebral inflammation. The patient may derive some benefit from this procedure, as the edge of bone removed may have produced some irritation, though it was not actually pressing inward as a definite ridge. The flap is replaced, but no sutures are applied. The proper treatment will be perfect rest, bromide of potassium, and active purgation, since every therapeutic measure must be directed to prevent the occurrence of meningitis. We have disturbed the parts very little, but inflammation is liable to occur after all such operations, which are only justifiable in obstinate cases of progressive epilepsy such as this.

. . . . . .

Notwithstanding the careful manipulation at the time of operation, the patient developed cerebral symptoms, and died at the end of a week. The post-mortem examination showed arachnitis, evidently resulting from the operation. The seat of the original fracture was occupied by membrane, to which the convolutions were adherent.

Progress of Medical Science.

The Nature of the Green Vomit.—The chemical and microscopical nature of green vomit has been made the subject of recent investigations by Dr. F. Betz (*Memorab., Monatschrift f. rat. prakt. Aerzte*, October 6, 1880). It was supposed that the green vomit (*vomitus æruginosus*) was the result of a greenish discoloration of brown biliary pigment, caused by the acid action of the gastric juice. The supposition received corroboration from the bitter taste of the vomited matter, associated with its acid reaction. Dr. Betz concludes, however, that the green color is not invariably due to the presence of bile. The color often varies from a yellowish green, or grayish green to a grass green, or dark green, in accordance with the greater or less amount of the "green substance" and other admixtures.

If green vomit be allowed to stand in a vessel, the greater part of the greenish substance will sink, whereas a small portion, containing slime and fatty matters will float on top. Shaking with water shows that the green substance is heavier than water and insoluble in it, a proof that bile is not the cause of the color. Agitation with chloroform or ether likewise demonstrates this, for neither fluid takes up the green substance. It may, however, be isolated by shaking with ether in a test-tube. This manipulation results in the appearance of three strata, an upper one consisting of ether, a middle one composed of the green substance, and a lower one containing the gastric mucus. Strong sulphuric acid produces a red color, strong nitric acid leads to a yellowish discoloration of the green substance. Acetic acid develops and fixes the green color very completely. Tincture of iodine produces a yellowish brown, and not a blue tint. Alcohol dissolves the green substance. In some respects it resembles the chlorophyll of plants. The alcohol dissolves it, and even retains the green color when boiled. The green vomit may be kept for months and during the hot season, without spontaneous putrid fermentation taking place—a fact which militates against the possibility of its biliary or even animal nature. Dr. Betz also states that sometimes the green vomit has a neutral or alkaline reaction. Microscopical examination showed the green substance to consist of an amorphous, finely granular greenish mass. Discoid heaps, or rounded colonies, are commonly observed. But the green substance may also form a lining over epithelial cells, salivary corpuscles, etc. From these facts Dr. Betz infers the vegetable nature of this substance, and he adds that it is probably derived from punctiform algæ, which he calls *chlorococcus*. He denies any relation of this low fungus to other microphytes such as the torula cerevisiæ, sarcina ventriculi, or oidium. Finally the author remarks, that apart from all other considerations, the frequent occurrence of copious green vomits would go to show that bile could not find its way into the stomach in such enormous quantity. The bitter taste of the green vomit receives its explanation in part from the frequent admixture of some bile, but is also in part due to the presence of a bitter principle in the chlorococcus.—*Memorab., Monatsch. f. rat. prakt. Aerzte*, October 6, 1880.

The Treatment of Aural Polypi.—Dr. A. Politzer (*Wien. med. Woch.*, No. 31, 1880) recommends the use of *spiritus vini rectificatus* as an excellent means of producing complete shrinkage of granulations and polypoid growths of the middle ear. Politzer proceeds as follows: First of all, the parts are thoroughly washed with tepid water, or in cases of suppurative otitis media, inflation by P's. method is practised. Next the ear is dried with absorbent cotton, and then the lukewarm alcohol is poured directly into the organ, the head being inclined to one side. The alcohol is allowed to remain in the ear from ten to fifteen minutes. Sometimes burning or smarting pains are produced. If the pain is severe, diluted alcohol is first used and its strength then gradually increased. The operation is repeated thrice daily.

Politzer found that the first effect produced by the alcohol consisted in blanching of the growth; then as the fluid penetrated the interior, vascular coagulation and, finally, considerable shrinkage occurred. Shrinkage was complete in some cases after a few days, generally in a few weeks, but sometimes not for several months. The soft round-celled polypi disappear more rapidly than those having a firm fibrous structure. But even the latter were frequently entirely effaced. The following indications for the use of alcohol are given by Politzer:

First.—For the removal of remnants of polypi in the external meatus, at the tympanum, and especially those in the middle ear, which cannot be reached by the knife.

Second.—In cases of multiple granulations of the external meatus and at the tympanum.

Third.—Excessive diffuse proliferation of the mucous membrane of the middle ear.

Fourth.—Cases not amenable to surgical interference, on account of mechanical obstruction.

Fifth.—As a tentative measure in persons fearing an operation, and in children, where surgical measures are often associated with extreme difficulties, and frequently require narcosis.—*Centralbl. f. Chir.*, October 2, 1880.

Cancer of the Rectum.—Dr. C. B. Kelsey, of New York (*New York Med. Journ.*, December, 1880), has made an analysis of one hundred and forty cases of excision of cancer of the rectum. This collection of reports was undertaken with a view to determine, if possible, the relative value of excision, as compared with lumbar colotomy. The following conclusions are drawn:

First.—The fatal results which have thus far been recorded as following this operation (excision) nearly all occurred in cases where, from the extent of the disease, such a result was not improbable.

Second.—When the disease reaches above three inches, or involves neighboring parts to such an extent as to render its entire removal without injury to the peritoneum questionable, the operation is contraindicated.

Third.—Although there have been a few cases of cure, such a result is so rare as not to justify the exposure of the patient to the risk of immediate death which attends the attempt to remove extensive cancerous disease.

Fourth.—The operation is chiefly valuable as a palliative measure, and as such it is applicable to cases where the disease has not made extensive progress.

Fifth.—As a palliative measure, in proper cases, it compares favorably with the results of lumbar colotomy, both in prolonging life and in relieving pain.

Sixth.—The operation is not followed by an annoying incontinence of fæces, except in a small proportion of cases.

Seventh.—The operation is not a substitute for lumbar colotomy in cases where the disease has reached more than three inches from the anus.

Eighth.—There is no proof that the operative interference shortens life by hastening the progress of the disease.

Sudden Death in Gangrene from the Entrance of Putrid Gas into the Heart.—In 1867 Dr. Parise sent a communication to the *Académie* which was accidentally left unpublished, but is now placed on record in the *Archives générales de médecine* (November, 1880). Parise observed several cases of sudden death in gangrene of the limbs, and in each instance believed that the fatal termination was brought about by the entrance of putrid gas into the veins, and hence into the heart. Maisonneuve had previously (in 1853) published several cases of rapid gangrene, with the development of putrid gas in the veins of the affected member. But he believed that death was caused by blood-poisoning from this source. Parise, however, affirms that the putrid quality of the gas determines no septic action, but produces death in the same way that air accidentally entering the veins does. In the cases reported by the author the autopsies were made soon after death, and a very careful examination revealed the abundant presence of putrid gas in the right side of the heart and the principal venous trunks.

Parise concluded, from the study of his cases, that surgeons should be on their guard against sudden accidents, especially in those cases of gangrene which follow a violent traumatism. Prompt action was necessary. Immediate amputation was the best curative procedure, and should be resorted to unless positively contraindicated by the conditions of the patient. In the latter case deep incisions might prove beneficial; or the principal vein might be ligated or merely compressed. Amputation below the point of ligation or compression would have to be performed sooner or later.

Foreign Body in the Pharynx Dislodged after Eight Years and Two Months.—In 1876 Dr. Singletary, of Arlington, Ky., was called to see a girl, aged seven, and found her suffering from broncho-pneumonia. About four years previously, while playing with a nickel penny, she swallowed it, and since that time had been a sufferer. Previously healthy and robust, after the accident she became delicate, had constant dyspnœa, and passed through several attacks of pneumonia. She ate very slowly and with great care, for she could not swallow any solid food. It was always necessary for her to have some fluid when she ate, that her food might be washed down. During the first year her throat was sore, and she vomited often, but with great difficulty. In April, 1880, she vomited about "half a gallon of pus" intermixed with "blood and corruption." This was just eight years, two months, and one day from the time of the accident. Twelve days later she passed the penny per anum. It was quite black and corroded, but still presented all the features plainly. It weighed eight grains less than an ordinary nickel cent, and as it was probably new when swallowed, it may have lost even more than eight grains. The girl is now well, hearty, robust, and playful; talking, eating, running, etc., just as other children. Dr. Singletary was unable to find a parallel case in the published records at his command.—*Louisville Med. News*, November 27, 1880.

Acute Blennorrhagic Vaginitis and Metritis Cured by the Application of the Tincture of Iodine.—This case was reported by Lastres (*El Siglo médico de Madrid*): A woman, aged thirty years, received the contagion from her husband. The initial symptoms were rather alarming; pulse, 100; temperature, 102 F.; severe lumbar and hypogastric pains, disuria, and pains in the right shoulder. The customary local and general treatment failed to produce any effect upon the virulence of the disease. A fortnight having elapsed, a speculum was introduced, and the cervix found red and tumefied. Tincture of iodine was then directly applied to it, and also brushed over the folds of the vaginal mucous membrane. No subsequent wash was used, and internal medication was suspended. On the following day a notable improvement was observable, and the applications of iodine were therefore repeated. The patient continued to improve and was soon completely cured.—*Le Courrier médical*, October 23, 1880.

Amputation of the Mamma without Loss of Blood.—In No. 30 of the *Centralblatt für Chirurgie*, of this year, Leisrink reported two cases of removal of the mamma, in which hemorrhage was avoided by the use of a clamp constructed for this purpose. This clamp was, however, thought to be suitable only for pendulous breasts. Dr. Szuman (*Centralb. f. Chir.*, October 2, 1880) communicates a new method for bloodless operations upon the mamma, with which he has been able to obtain excellent results. He utilized the principle which underlies the application of successive ligatures to broad pedicles in ovariotomies. The author states, however, that his method is applicable only to those cases of mam-

mary neoplasms which are still movable at their basal surface. From the detailed account given of an operation involving a highly vascular pigmentary cancer, and which illustrated the efficaciousness of his method, we gather the following: A long and straight needle of large calibre, armed with a heavy double silk ligature previously carbolized, is thrust through the mamma from above downward and parallel with the surface of the thorax. The ligature is then cut at some distance from the point of exit, and the first portion of the gland tied off. By repeating this manipulation a sufficient number of times (four times in the case described), the entire base of the gland is secured between the tightly drawn ligatures. The tumor, in this instance, assumed a dark, purplish hue, but on being removed by the knife not the slightest hemorrhage occurred. There is no danger of wounding the pleura if the needle is carefully used, and if the narcosis of the patient is sufficiently deep to prevent the occurrence of sudden movements.

Dr. Stukowenkoff, in the same number of the *Centralblatt*, states that for the past two years he has been in the habit of using a clamp exactly like the one described by Leisrink. He adds that he also applied a tight ligature behind the clamp, in order to cut off the lateral portions of the tumor from blood-supply.

Pigmentation of the Giant-Cells of Tuberculosis.—At a recent meeting of the Société de Biologie, of Paris, M. Cornil stated that he had frequently found the giant-cells of tuberculosis impregnated with black granules or pigmentary matter. The latter substance was doubtless produced by transformation of the coloring matter of the blood, and was most frequently observed in connection with fibroid phthisis. In microscopic sections these granules appeared disseminated through the bodies of the cells. Sometimes such molecules were rounded, at others they had a polygonal shape. Occasionally the nuclei of the giant-cells were replaced by little collections of carbon or pigment. Sometimes the entire cell would appear filled with these black deposits. The power of resistance, and longevity of giant-cells was, he thought, due to this infiltration.—*La Tribune médicale*, October 31, 1880.

Treatment of Hepatic Abscess by large Incisions under Lister's Method.—A recent communication to the Académie de médecine by Dr. Rochard, contains the following points: Local pain is felt only when the pus has approached the surface of the liver, thus causing a perihepatitis. Sometimes a voluminous abscess will be found at an autopsy, when vital symptoms of its existence were never obtained. Reflex pain in the right shoulder is no characteristic symptom. In most cases the hepatitis follows dysentery or other diarrhœal affections. The affection may be suspected when a person having suffered from enteritis develops fever, is troubled with his digestion, and shows an enlarged liver. When the febrile movement assumes the hectic type the formation of pus may be known to have occurred, and explorative puncture should not be delayed. Frequently it becomes necessary to make several such punctures before pus is detected. This is a harmless procedure. Pus having been found, a large incision parallel with the direction of the ribs should be at once made. The cavity of the abscess is then to be washed out with carbolized water until thoroughly cleansed. Then a large drainage-tube is inserted deeply into the wound, secured in its position, and then covered over with the Lister dressing. This is to be removed once a day, the drainage-tube being also removed for cleaning at each time, and reinserted after having been shortened to correspond with the shrinkage of the cavity. In the three cases described by Rochard this shrinkage was remarkably rapid, and it was associated with a return of the patient's appetite, a permanently febrile condition, and a corresponding amelioration of the patient's general health. The facts relating to these cases were obtained from Dr. Little, of the Shanghai Hospital, and a French marine surgeon who had himself undergone the operation. A fourth successful case, reported by Mac Lean, was also alluded to.—*Bulletin de l'acad. de méd.*, October 26, 1880.

Actinomycosis in Men and Animals.—Ponfick, of Breslau, has recently called attention to an interesting condition that he has observed in five individuals, all of which were affected with a peculiar disease of the bones, and exhibited coincidently peculiar yellowish granules in the discharges from the site of the lesion. The following instance is given as a typical exemplification of the malady in question: A blacksmith, aged forty-five years, was in hospital under treatment for a destructive spinal difficulty, when it was observed that there were peculiar granules, both in the pus that was escaping through the fistulous tracks and in the gelatinous matter that lined them. They appeared about the size of lycopodium particles, and were evenly disseminated in the morbid material. P. regarded them as identical with the bodies observed by Bollinger in the so-called actinomycosis of horned cattle. In directing his attention to this latter disease, he found that it was known as "worm" in Hanover and Silicia, and was by no means uncommon. It usually has its site at the angle of the jaw, where, after a while, fluctuating tumors, often the size of one's fist, are developed. When incised such masses contain no pus, but exhibit a hollow interior filled with granulation material, in which the yellow particles above described are infiltrated. Sometimes they ulcerate and then simulate sarcomas. In their further progress the neoplasms pierce the bone, and then dilate it, producing the appearance of a true *spina ventosa*. The disease is also common among hogs, but not among the pure carnivora. Ponfick has observed that the disease is associated most frequently, perhaps, with inflammation about a tooth. Proceeding from this point metastases have been found in the spinal column. In all the instances thus far recorded there has been a fatal issue. Most of the individuals affected had nothing to do with horned cattle, though remarkably enough one of them had been frequently about an animal with this peculiar disease. The specimens had been exhibited to botanists, who regarded the granules as vegetable parasites. Still, they could give them no classification, and all efforts to cultivate them artificially had proved futile.—*Centralblatt f. Chir.*, November 20, 1880.

Anæsthetic Effects of Chloroform and Ether.—Mr. Newman contributes a report on the effects of anæsthetics on the pulmonary circulation, in the *Journal of Anatomy and Physiology*, July, 1880, from which it appears that while chloroform in seventy-five seconds stops the pulmonary circulation, and requires 600 cubic centimetres of air and 720 seconds to restore it, it requires ten times as much ether and takes 270 seconds to produce the same effect, which is removed by 200 cubic centimetres of air in 180 seconds.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 8, 1881.

THE PROGRESS OF THE METRIC SYSTEM.

An item has been circulating through the medical journals of late, intimating that the attempt to introduce the metric system in this country is a failure. All the old objections to the system are rehearsed, and some of our esteemed contemporaries have boldly announced that its principle is wrong, its various features complicated and unscientific, and its adoption among us an impossibility. A great deal of capital is made of the fact that the standard French metre is not the exact fraction of a meridian which it was first thought to be. But this can make no difference as long as a fixed standard is obtained and kept accessible for reference.

We are inclined to think that the future of the metric system is not so dark as is represented. There is not so much said about it in the medical press, to be sure, but even the most ardent champions may be expected to like a little rest. During the past year the British Medical Association has taken active steps to secure the adoption of the system, and in England it has encountered no active opposition. In this country the American Medical Association, last June, received, through its president, the endorsement given to the system in previous years. At that time a fact was cited which no theoretical cavillers can get over; it was this—that in the organization where the system had been practically and extensively applied, namely, in the Marine Hospital Service, it had proved an unqualified success. Such testimony as this outweighs all the diatribes that have been uttered against it by those who, it must be believed, have little knowledge and less actual experience of its workings.

It will be noticed, furthermore, that nearly all visiting lists, call-books, dose-books, etc., as well as works on materia medica, are now being printed with metric equivalents. In many medical colleges it is now hardly possible for the student to learn, or the instructor to impart, such branches as histology, physiology, chemistry, etc., without introducing the metric system.

The metric system, indeed, is irrevocably fixed upon scientific medicine. It is used by nearly all nations but the Anglo-Saxon. It is woven into the largest part of medical literature, and is already adopted everywhere by those engaged in scientific studies, whether medical or otherwise. It is now the common language of measurement among scientific men, just as the Latin language was the common language of scholarship three centuries ago. A system thus widespread and thus endorsed by men accustomed rigidly to weigh the merits of the tools and appliances they deal with, cannot be the absurdity which certain parties claim. The metric system must be learned by the educated physician, and will, we believe, eventually be practically adopted by him. Perhaps there have been efforts to force the matter too rapidly upon the profession. It certainly will take a long time and perhaps wiser methods than have yet been used to secure its final adoption. But all this does not lessen the fact that the metric system is the most widely established and most rational method of measurement. And it is no sign of its failure that it has not become popular on the shores of a great lake. The cackle of the burgh is not to be mistaken for the murmur of the town.

THE PAY OF HOSPITAL STEWARDS.

A bill has been introduced into Congress by the Hon. J. A. Osmer, which proposes to increase the pay of hospital stewards from the present sum of thirty dollars monthly to fifty dollars. We have examined the provisions of the bill and the reasons assigned for its introduction. It appears to be an eminently just measure, and we trust that the medical staff of the army will see that it becomes a law. The duties of a hospital steward involve a knowledge of practical pharmacy, as well as good clerical and executive ability. Besides this, he is often required to know something about minor surgery, dentistry, and perhaps cooking. His duties, indeed, are so various that a manual of three hundred and twenty-four pages has been published for his instruction and use.

The pay of thirty dollars a month, with quarters, etc., seems quite inadequate to secure permanently the kind of men who are most desirable for such a position. At any rate, it is a much smaller sum than is paid for less skilled labor in other branches of the service. The hospital stewards of the United States Marine Hospital Service receive fifty dollars a month, and even the pay of assistant stewards in that service is greater than it is in the army. The naval service has "apothecaries," with duties similar to

those of hospital stewards. These officers receive sixty-five dollars a month.

Coincident with the proposed increase in salary, the bill we have referred to establishes a competitive examination by a medical board, to which all candidates for stewardships must submit before they can get an appointment. The tendency of the bill thus is to secure a better class of men as officers. We commend the measure, therefore, to the attention of the officers of the service as being one that deserves their support.

DIET FOR THE SICK.

The physician who has but a theoretical or hearsay knowledge of drugs is but little above a dreamer, and we should certainly regard him as an unsafe man who, in a given case, would direct the nurse or the apothecary to give his patient a tonic, a cathartic, or a neuretic. There are many disorders, conditions, and diseases in which the diet is fully as important as, or more important than the medication, and yet it but too often happens that the physician tells the attendant to let the patient have a little light food or some soup, leaving to the discretion of the nurse what it is to consist of, how it is to be prepared, or in what quantity it is to be taken. We need not remind our readers that nothing that concerns the welfare of those intrusted to his care is too trivial for him to notice.

That the value of a knowledge of the preparation of food for the sick is beginning to be appreciated by the profession, is shown by the almost simultaneous appearance of two works* upon the subject; one by an experienced nurse, the other by distinguished therapeutists. The former is necessarily empirical, while the latter proceeds inductively, reasoning from physiological principles; and while they differ in many respects, yet there is a remarkable similarity between the conclusions reached regarding the proper food-constituents and the best mode of preparing them. They will both be found, if properly used, to be great aids in practice. It is of course not intended that the doctor shall go into the kitchen and direct the cook, but that he should understand enough of the constituents of articles of diet to select them intelligently and to give directions as to the best methods of their preparation. In other words, such a knowledge enables him to give the prescription for the food just as he would give the prescription for the medicine.

ABSINTHISM.

It was about one hundred years ago that a certain French refugee, named Dr. Ordinaire, came to Val Travers, in Switzerland, and there began to practise his profession. One of the results of this small incident is, that France now receives from Val Travers and the country thereabouts, 80,000 gallons of liqueur d'absinthe yearly, besides manufacturing perhaps a larger amount in her own borders. Considering the havoc which this elixir has made upon the constitution of so many of her citizens, we may wonder if France could have possibly made a worse selection when she chose to expatriate Dr. Ordinaire.

This gentleman was a regularly educated and skilful physician, though, perhaps, too much given to panaceas. One of his specially popular remedies was a preparation made from the *artemisia absinthium*, a herb which grew in great abundance in the locality where he lived and which had long been much used in domestic practice. By this mixture Dr. Ordinaire grew famous. At his death the secret of its preparation was sold to parties who continued its manufacture. Under the name of Liqueur or Extrait d'Absinthe, it became widely known. In 1830 the artemisia herb-crop alone was worth 88,000. The liqueur began to be extensively used in France a few years later. The habit of absinthe, drinking soon became and still is very prevalent in that country, especially among the better classes. It prevails also in Germany, England, and in the United States, though to a less extent than in France. In London the liqueur is advertised in many places. In New York it can be had in any of the larger saloons.

The fact that the use of the liqueur causes serious damage to the system has long been known, and the special morbid effects have been carefully studied by several observers, among them Marcé Amory, Maquan, and others. Quite recently some papers on the subject have been presented to the French Academy of Medicine by M. Lancereaux; they represent the results of his studies of acute and chronic absinthism.

Absinthe, in small doses, causes a sense of exhilaration something like that produced by alcohol. In larger doses there is giddiness, mental oppression, or later, mental excitement, and the end may be in convulsions which are very rarely fatal. These convulsions have always been considered to be epileptiform in character, as they are in appearance. M. Lancereaux, however, in his recent memoir, asserts that they are hysterical. He says also that the symptoms in chronic absinthism are more allied to those of hysteria than to those of any other disease. These symptoms are various, but in general it will be found that the absinthe tippler suffers from muscular weakness and tremblings; there is a loss of appetite, apathy, melancholia, and hallucinations. The end is often in some structural derangement of the liver, stomach, or nervous system. Insanity is said to be the direct result in some cases; indeed, about one-fourth of the cases of insanity among French officers are traced to the use of absinthe. The drug seems

* Invalid Cookery, etc. By Mrs. Julia A. Pye. Edited by Mrs. Eliza A. Pitkin. Pp. 127. Chicago, 1880: Food for the Invalid, etc. By J. Milner Fothergill, M.D., and Horatio C. Wood, M.D. Pp. 157. New York: MacMillan & Co., 1880.

to transmit its impress with great uniformity to the succeeding generation. Nearly all the children of habitual absinthe-drinkers have some physical defect. With such manifest evils attending its use, one naturally inquires what are its fascinations. The liqueur d'absinthe is composed of alcohol, oil of wormwood, anise, dittany, angelica, and other aromatics. It is a greenish liquid, and tastes very much like paregoric and water. It is hardly to the palate, therefore, that it appeals. It gives, however, a peculiar kind of exhilaration, and this effect, together with the fact that it is a fashionable drink among a certain class, must account for its popularity. Its use is said to be increasing in France and some other countries of Europe. It is not, we think, a drink which will become very popular in this country; indeed, as far as can be learned, the sale of it in New York is hardly as great now as it has been. But it is a serious evil in France, as is shown by the attention given it there by those engaged in sociological and in scientific studies.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 16, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

Dr. John M. Cuyler, of the U. S. Army, was elected an Honorary Fellow, and Prof. Jean M. Charcot, of Paris, a Corresponding Fellow of the Academy.

The paper for the evening was read by DR. ALEX. J. C. SKENE, of Brooklyn, and entitled

THE RELATION OF THE OVARIES TO THE BRAIN AND NERVOUS SYSTEM.

That the sexual organs exercised important influences upon the brain and nervous system in health and disease was recognized, in a general way, by medical authorities. There was, however, an obvious lack of exact knowledge upon the subject, especially in regard to the share which individual organs of the sexual system contributed to the sum of such influences. Therefore, his contribution was offered toward the elucidation of one section of that subject, namely, the relation of the ovaries to the brain and nervous system.

That one organ, and indeed one part of an organ, exercised a higher and better defined influence upon the rest of the organization than another, was a fact beyond question. It was well known, for instance, that the cervix uteri was less potential in affecting the nervous system than the body of the uterus. The gynecologist might wound, cauterize, or amputate the cervix without exciting violent pain or inflammation; but he found less of security from danger in dealing with the body of the uterus. The speaker referred, first, to the physiological relations of the ovaries to the other sexual organs, and said that the function of the ovaries was primary in the process of reproduction. Their physiological activity preceded the uterine functions and continued, as a rule, until the menopanse, and possibly after it. Hence the functions of the other sexual organs appeared to be responsive to the influence of the ovaries. There were, however, differences of opinion concerning that question.

Observations had been made which showed that ovulation and menstruation occurred independently of each other, in exceptional cases at least, and a high degree of importance had been given to that, apparently, independent action, but such irregularities were the exception, not the rule. There were facts in abundance to prove that, when the ovaries were absent or rudimentary from birth, the function of the uterus was never established, and the removal of the ovaries after puberty arrested menstruation in the majority of cases. All that we knew regarding the influence of the ovaries upon the development of the individual and the exercise of the sexual functions throughout the reproductive period of life, pointed to the conclusion that those organs were the prime movers in the sexual system. If we accepted the idea that the ovaries were essential to the very existence of the sexual system, and that their office was the highest and the first in the order of events which collectively made the complete process of reproduction, it was easy to understand that their absence would arrest the action of the whole system. They were paramount, not subordinate in reproduction, and in the maintenance of the relationship between the general and the sexual systems the ovaries were undoubtedly the most potential. The uterus and vagina were superadded structures, rendered necessary by a more complex and perfect system of reproduction in the higher species.

Dr. Skene then referred to Dr. Henry Maudsley's book on "Body and Brain," and quoted that author's high estimate of the relationship which existed between the ovaries and the general system, especially with reference to the development and function of the brain and nervous system.

Virchow and others had stated that the ovaries gave to woman all her characteristics of body and mind, and Dr. Skene accepted the proposition without qualification, feeling sustained in doing so by the fact that, when the ovaries were absent or defective from birth, the characteristics of the female sex were never fully developed. The tendency in the development of those in whom the ovaries were congenitally absent was toward the masculine type of the race.

Among the authors who appeared to stand in opposition to what was just claimed, Dr. Goodell, of Philadelphia, was mentioned, who maintained that "beyond the induction of sterility and the probable absence of menstruation, the deprivation of the ovaries after puberty does not change the character of the woman." Dr. Goodell had quoted Battey, Hegar, Wells, and Peaslee as confirming his opinion. But the views held by the last named authors were based upon observations made upon mature women, from whom the ovaries had been removed. That alone, however, Dr. Skene believed, was not a trustworthy source of information, because the results obtained up to the present time appeared to be quite variable. Those authors reasoned from the effects produced by the removal of the ovaries from mature women, while Dr. Skene reasoned from the facts observed in women born without ovaries.

In that connection, reference was made to the influence which the nervous system exerted in controlling the functions of reproduction, and special attention was directed to the fact that the sexual

organs were dependent upon the general nutritive system for organic support, and that they stimulated, depressed, or modified nutrition through the ganglionic nerves chiefly, and that the portions of the brain which presided over the organic functions also dominated over the reproductive organs.

In view of this great potentiality of the ovaries in developing certain capabilities of the brain and nervous system, and in influencing their functions, it was evident that, in order to maintain harmonious action of the whole organization, it was necessary that the ovaries should exist in full development and functional activity. On the other hand, those organs which were so essential to the well-being of the individual must, when diseased, exercise a potent influence in deranging the brain and nervous system.

From a somewhat extended consideration of the subject, he was satisfied that a great many affections of the brain and nervous system were due to disease of the ovaries.

When a woman was deprived of the sexual organs, the nutritive system might possibly attain a normal development, but the nervous did not, and remained upon a lower plane. There was usually mental weakness and often derangement of mind, among those in whom the ovaries were imperfectly developed. Among sixteen young single women who came under his observation in the Insane Asylum, twelve had imperfectly developed sexual organs, and the histories of the cases led to the conclusion that the defective development of the ovaries was an important element in causing their insanity. They no doubt inherited an insane diathesis, but the absence of ovarian influence, which favored a higher and more complete development of the nerve-centres, acted presumably as the major cause in producing the insanity.

Dr. Skene then spoke of the effect produced on the nervous system by derangements of menstruation, and felt convinced that conditions of the ovaries which deranged the menses affected the nervous system far more than the dysmenorrhœa due to abnormal conditions of the uterus. The symptoms of ovarian dysmenorrhœa, so called by some writers, were then reviewed.

With reference to other diseases of the ovaries, he believed that displacements and inflammatory affections of the ovaries produced remote effects more grave than disease of any of the other pelvic organs. The symptoms attending those two conditions were then studied.

The nature of many of the diseases of the ovaries and their clinical history being imperfectly understood, it naturally followed that, in that department of medicine, the art of diagnosis fell short of the demands of every-day practice.

It was often very difficult to determine the character of some ovarian diseases, and to estimate the effect exerted by them upon the nervous system. All forms of morbid nervous phenomena might arise from causes other than disease of the sexual organs, and hence there were no constitutional symptoms that were diagnostic of ovarian affections. It became necessary, therefore, to determine first that disease of the ovaries existed, and then to estimate how far the nervous symptoms were dependent upon the local affection. In all the inflammatory affections of the ovaries, a fair degree of accuracy could be obtained in diagnosis from the symptoms and physical signs of ovaritis, such as were given in our text-books, and the same could be said concerning displacements of the ovaries. Upon the latter point special reference was made to Dr. Paul F. Mundé's paper in the fourth volume of the "Transactions of the American Gynecological Society."

In the more grave diseases of the nervous system, such as epilepsy and nymphomania, which had been presumed to be due to ovarian disease, the diagnosis was sometimes exceedingly difficult. There was, perhaps, no problem in gynecology more difficult to solve than that, and very much depended upon its correct solution. With reference to treatment, the majority of patients who had simultaneously ovarian disease and nervous affections required both local and general treatment. The paper was closed by giving the histories of five cases which illustrated the position of its author.

The paper being before the Academy

Dr. Allan McLane Hamilton remarked that he had listened to Dr. Skene's paper with great interest, and believed it to be an admirable exposition of the gynecological side of the question.

He had met with many cases in which the ovaries had much to do with the production of nervous disease, not only indirectly but in connection with the direct production of convulsive attacks. He differed with Dr. Skene in his interpretation of Charcot's term hystero-epilepsy, which was used by the latter to describe the combination of a convulsive seizure and a stage of mental excitement, and did not necessarily imply that there was uterine disease.

Dr. Hamilton also referred to an interesting rôle played by ovarian disease in the production of grave organic diseases of the spinal cord, the primary condition being a hysterical paraplegia. He had known of only four or five of such cases, two of which were described by Charcot, and one by Briquet, many years ago. He had lately seen a case with Dr. Mundé, in which dislocation of the left ovary existed with a most profound hysterical condition. There had been an hysterical paraplegia for some years, the patient being twenty-one years old. Three or four years ago the symptoms of primary sclerosis of the lateral columns became added to those already present. She now presents a decided rigidity of the lower limbs, spastic contraction, the dorsal clonus, and other well-known phenomena. There was no anæsthesia, and the action of bowels and bladder were unimpaired.

At the menstrual periods the symptoms were much more pronounced. She then had constant hysterical vomiting, pain, and other curious symptoms. The slightest touch upon the cutaneous surface provoked the trepidation in her lower limbs, and tickling the soles of the feet gave rise to violent headache. There was no reason to suppose the trouble came from any other cause, and her family were free from nervous disease. Dr. H. was of the opinion that the ovaries played an important part, so far as epileptic and hysterical attacks were concerned, and alluded to the effect of pressure upon the ovaries in the latter.

Dr. Paul F. Mundé remarked that the author of the paper had discussed the subject so fully, but little remained to be said, and his references would therefore be chiefly corroborative. It has been claimed by Dr. Skene that disorders of the ovaries were much more frequently the cause of affections of the nervous system than were diseases of the uterus; yet, if that was true, it was important not to overlook the uterus.

Dr. Mundé thought that Dr. Skene was quite right in his belief that oöphoritis very frequently gave rise to symptoms referable to the nervous sys-

tem; and yet chronic inflammation of the uterus might give rise to similar, if not the same symptoms, when there was no disease whatever of the ovaries. Again, Dr. Skene had stated that the female did not attain to perfect development unless the ovaries were also fully developed; but Dr. Mundé thought that the statement admitted of some doubt. There were several cases on record in which persons were perfectly developed, generally and locally, and yet had neither ovaries nor uterus. Such cases had been reported by Chambers and others.

With reference to prolapsus of the ovaries, Dr. Mundé mentioned that there were several cases recorded in his paper to which Dr. Skene had referred, in which prolapsus of the ovary itself seemed to be the cause of the nervous diseases from which the patients were suffering. He then gave the histories of two cases in which reduction of a prolapsed ovary was promptly followed by an amelioration, and soon by a complete disappearance of all nervous symptoms. With reference to treatment, it had been thus far rather unsatisfactory. He had given considerable relief by painting the wall of the vagina near the affected ovary with plain tincture of iodine, by using hot vaginal injections and the glycerine tampon, and by maintaining external irritation with blisters and iodine.

For the relief of the constitutional symptoms, he had seen good results follow the use of the chloride of gold and sodium. The bromides, also, were beneficial, and so was electricity, especially where there was lack of development of the ovaries.

Dr. Holcombe referred to certain cases which illustrated effects produced upon the eyes by genital irritation, especially onanism. He doubted the accuracy of the statement that certain portions of the brain presided over certain functions.

Dr. W. R. Birdsall referred to experiments performed upon dogs by Röhrig, who ascertained that contractions, occurred in the uterus and blood-pressure was increased when the ovaries were irritated with the electric current; that no evidence of sensibility was produced by the external surface of the ovaries, but that when the uterus was irritated movements as though the animal was suffering from pain were quite evident. In other words, Röhrig's experiment proved that the uterus is far more sensitive than the ovaries.

Dr. L. Putzel remarked, with reference to Dr. Skene's sixteen cases of insanity and the twelve in which evidence of disease of the ovaries was found, that he had made about ninety post-mortem examinations at a lunatic asylum, and did not recall a single case in which disease of the ovaries existed.

He also directed attention to Dr. Israel's case of hysteria in which various uterine medication had been resorted to without benefit, and finally it was determined to perform Battey's operation. The patient recovered entirely, but incision was made only through the abdominal walls, and the ovaries were not touched.

He also referred to a case of catalepsy, occurring on Blackwell's Island, in which Battey's operation was performed. The patient died of peritonitis, and upon microscopical examination the ovaries were found healthy.

With reference to epilepsy occurring with the menstrual periods, he believed that in many of those cases a hereditary influence existed which gave a more rational explanation of the occurrence of the convulsive affection than congestion or disease of the ovaries, and that the physiological condition of the ovaries acted each month merely as an exciting cause of the epileptic seizures.

Dr. Skene, in closing the discussion, said that the remarks made had been so pleasant in tone that perhaps it would be wisdom upon his part to rest his case without further argument.

With reference to Dr. Hamilton's remarks he would say that he had always made a clear distinction between those cases in which there was organic disease of the ovaries and nerve-centres so related as to make their inter-dependence certain, and those in which there was disease of the nervous centres and functional affections of the ovaries, the relations of which were difficult to diagnosticate.

In some of the cases referred to in the paper there was no definite evidence of disease of the ovaries present, and yet the patients had hystero-epilepsy, presumed to be due to ovarian influence. Those were the cases which he desired to bring forward for investigation.

With reference to the cases referred to by Dr. Mundé, the fact that glandular organs, like the testicles rather than like the ovaries, were found, was sufficient to make them favor rather than oppose Dr. Skene's doctrine, that the mental and physical characteristics of sex depended for their development upon the essential organs of reproduction. There was no case, in the literature of any country, so far as he knew, in which there was any evidence whatever of sexual characteristics in the absence of ovaries or testes. Dr. Skene, therefore, thought that he could reasonably claim the cases cited by Dr. Mundé as favoring his own views.

With reference to Dr. Holcombe's question, Dr. Skene remarked that he took special care *not* to state that certain portions of the brain remained undeveloped when the ovaries were wanting, but that certain capabilities of the brain were never manifested. He, on the contrary, stated that he did not know the location of that portion of the brain which presided over the sexual functions.

With reference to the experiments performed by Röhrig, and referred to by Dr. Birdsall, they were of great value as showing the possibility of demonstrating the relative influence which existed between the sexual organs and the nervous system.

With reference to Dr. Putzel's criticism, he had misunderstood Dr. Skene, who said that the ovaries in his cases were either imperfectly developed or functionally inactive. The text of the paper plainly stated that he did not claim that the only cause of insanity in the cases cited was defective ovarian development. An inherited predisposition to insanity was recognized. He was also sure that ovarian disease, as a cause of epilepsy, was of little account compared with transmitted peculiarities of organization. He doubted if either the absence of ovaries or the presence of ovarian disease would produce epilepsy in cases in which there was no constitutional tendency to the convulsive affection.

Dr. Skene thought that, on the whole, he claimed less for the sexual organs than other observers had done. He simply desired to prove that the ovaries were the most potential elements of the sexual system, in their influence upon the nervous system.

Regarding the large number of cases examined post-mortem by Dr. Putzel, he would say that although the doctor found the ovaries apparently normal in structure, that did not prove that the sexual organs had nothing to do in the cause of the insanity. The ovaries might have been normal in structure, but deranged in function during life in

many of the cases. If his cases were all free from structural and functional diseases of the sexual organs, they were exceptional. He had never seen seventy-five insane women in middle life, taken as they came, without full derangement of the sexual organs among a large number of them.

On motion by Dr. Foster Jenkins the discussion of Dr. Skene's paper will be continued at some future meeting called by the President.

The Academy then adjourned.

CLINICAL SOCIETY OF MARYLAND.

Stated Meeting, held in Baltimore, November 5, 1880.

T. S. Latimer, M.D., President, in the Chair.

EXTENSOR PARALYSIS OF FOREARM TREATED BY ARTIFICIAL ELASTIC EXTENSION.

Dr. John Van Bibber exhibited a patient who, in consequence of the pressure exerted on the musculospiral nerve by allowing the arm to hang over the back of a chair while asleep, had incurred a complete paralysis of the extensor muscles of the right forearm. He came under Dr. Van B.'s treatment one week after the accident. The treatment consisted of the constant wearing of a rubber band extending from the elbow to the knuckles, being attached at each of these terminal points. This furnished an antagonistic force to the unimpaired flexor muscles, and gave exercise to the extensors. Added to this, massage of the limb eight or ten times a day and the faradic current of electricity were employed. The result was that after ten days of such treatment the patient was able to resume work. He is now (after seventeen days from the commencement of the trouble) able to do five days' work in eight days. The usual time of treatment of extensor paralysis is three to five months. The arm is much larger and muscles much firmer than on the well side, and the affected muscles respond readily to slight electrical currents. The interesting point in the treatment is the observation concerning the compensating effects of the will and the faradic current. In such peripheral paralyses the paralyzed muscles always react under induced currents of electricity, and if the current is tinely interrupted the muscles respond in a complete state of spasm. If milder currents are used the result is not so marked, and the muscles respond only with a slight agitation. He has adopted the plan in this case of asking the patient to contract the flexor muscles at short intervals during the application of the current, and immediately on ceasing this movement the hand becomes extended under the influence of the electrical spasm. This would be repeated some twenty or thirty times, until the paralyzed group was exhausted or no longer responded to the current.

This procedure causes a decided change in the circulation of the damaged muscular area, and gives the paralyzed group an exaggerated amount of exercise.

At the end of six days' treatment, improvement had so far progressed that the patient was able to raise the hand to a slight extent, showing by this indication that, whatever may have been the morbid condition of the nerves, it had now been overcome sufficiently to allow influence of the will to pass over the injured portion. After this improvement had been noticed the patient was examined before each application of the current in regard to the possible movement in the extensor muscles. The muscles were then tested for faradic reaction by slight currents. While the patient remained perfectly passive the diminished current would draw the hand up horizontally with the arm. If during the application of the same current the patient was asked to move his extensors as much as possible, it was found that the injured muscles acted with more force and extended the hand much above a line horizontal with the forearm. These experiments were repeated often and always with the same result, viz., that a slight current, supplemented by the will, would bring on much better contraction than either the electricity or will-power acting alone. This is another proof of the necessity of treatment to the paralyzed muscles, in order that when the impediment in the nerve is overcome the muscles may be in better condition to resume their natural functions.

EXTRA-UTERINE PREGNANCY—FETAL BONES PASSED PER RECTUM—DEATH ONE MONTH AFTERWARD.

Dr. Atkinson reported the following case: In 1872 he attended a young colored woman, who was supposed to be about five months pregnant. She was then suffering from symptoms of subacute peritonitis; these continued to term, her pregnancy otherwise being normal and exhibiting nothing calculated to excite suspicions of unnatural pregnancy. In February, 1872, he was called to attend her in her confinement. He found the os dilated to the size of a silver quarter. The fetal heart was audible and fetal movements were perceptible, both to himself and to the mother. While in this condition he was called away from her, and did not see her again until the following April, when he was told that, after lying in bed a month and discharging some bloody liquid from the vagina, she had gotten up and gone about. Examination satisfied him that there was a dead fœtus in the abdominal cavity. She was not seen again until May, 1880, having meanwhile gotten along pretty well. He now discovered a tumor in the right iliac region, about the size of a cocoanut. She suffered much pain, and could not bear the least pressure, symptoms which were attributed to peritonitis excited by the unnatural position of the child. Her pulse was 120–140, and temperature 102° F., and her condition was extremely unpromising. She had been treated by her previous attendant for typhoid fever. Dr. A. continued to treat her for the peritonitis for several months. In September, 1880, during his absence from the city, she had a severe pain accompanied by some obstruction of the bowel near the anus; this led her to introduce her finger into the anus, from which she drew out a bone. Shortly after Dr. Page extracted another bone lodged transversely in the rectum. The patient died of exhaustion about one month afterward. The two bones proved to be the inferior maxilla and ulna of a fœtus. Dr. Atkinson said that he had reflected seriously upon the propriety of operative interference in this case, but had concluded that it was better to let it alone.

Dr. B. Bernard Browne said it was an interesting question whether it was a case of primary extra-uterine conception, or due to rupture of the uterus at the time of labor. Cases are not very infrequent in which the fœtus becomes encysted; the woman may even bear children while carrying an encysted fœtus. The diagnosis of this is very difficult.

Dr. Erich said a number of these cases had been reported within the last few years, in which the women were relieved by operation. If the diagnosis were satisfactorily made out and the patient were suffering, we had better operate; many cases could

thus be saved. The great danger of the operation is in disturbing the placenta, which ought not to be meddled with.

If, in the case under discussion, the opening into the rectum through which the bones were discharged could have been reached, the patient might possibly have been saved by a complete removal of the fœtus and careful washing out of the cyst with carbolized water.

Dr. Claude Van Bibber alluded to a case reported by his father, Dr. W. Chew Van Bibber, in the *American Journal of the Medical Sciences*, 1858, in which the whole fetal skeleton was removed by the rectum four years after the symptoms of labor.

THREE CASES OF PROBABLE RUPTURE OF KIDNEY.

The first case, reported by Dr. O. J. Coskery, was that of a brewer, who fell a distance of thirteen feet upon his right side. This was followed by profuse hemorrhage from the urethra and collapse. On examination, besides other injuries there was fracture of the last two ribs on the right side, and an ecchymosis extending from the ribs to the crest of the ilium. Reaction was established under the use of stimulants by the second day, but the patient continued to pass bloody urine until the third day after the injury. Excluding other possible causes of hæmaturia, and taking the above facts into consideration, particularly the reception of the chief force of the fall over the region of the kidney, and the pain felt over the organ on deep palpation for some days after the complete clearing of the urine, Dr. C. felt justified in inferring a rupture of the kidney. The patient recovered.

The second case was that of a carpenter, who fell, with some beams and planks, thirty-five feet. He was very much bruised, especially over the region of the right kidney. At the end of twenty-eight hours, no urine having been passed, a catheter was introduced, which gave exit to clear urine, gradually changing to blood. He had no chill or pain, but the abdomen became tympanitic. The urine continued bloody until the sixth day. He returned to work on the thirteenth day.

In the third case the injury was inflicted over the left kidney by the kick of a mule, giving rise to a copious hæmaturia, which continued for ten days. The patient was discharged apparently well, but in a few months became an inmate of the almshouse, with symptoms of pus and hyaline casts in the urine, hectic fever, gradual emaciation, and sudden death. On post-mortem examination, the immediate cause of death was found to be enormous distention of the pericardium with fluid. A large abscess was found on the left side under the subperitoneal fascia, beneath and around the kidney, which was atrophied. The pus had burrowed in the tissues around extensively and had perforated the colon. There was apparently no communication between the abscess and pelvis of kidney.

Dr. Atkinson asked if there was anything in medical literature bearing upon this subject.

Dr. Coskery replied that it was alluded to by both Bryant and Erichsen.

Dr. Tiffany said a case almost identical with the last one reported in Dr. Coskery's paper was to be found in Cooper's Surgical Dictionary.

Vivisection Again.—Mr. Henry Bergh delivered a free lecture on vivisection at Association Hall on the 3d inst.

Correspondence.

LIME-WATER IN DIPHTHERIA.

To the Editor of The Medical Record.

Dear Sir—My attention has been called to the following remarkable passage occurring in a recent publication of Dr. A. Jacobi:

"Dr. Billington takes exception to my remarks on the inefficiency of lime-water, made before the New York Academy of Medicine on the occasion of the doctor's reading a detailed account of forty cases of diphtheria. In an open letter to the editor of the Medical Record, over his name and address, he says it occurred to him that the question might be answered by a very simple experiment. He says: 'I was permitted by a patient, who has an unusually patent and tolerant throat, to hold a bit of red litmus-paper at the end of a wire, and protected from the action of the saliva by coils of wire, well back in the pharynx, the patient being instructed to breathe naturally. I then, with the atomizer which I use in treating diphtheria, and in exactly the same manner, threw the spray of lime-water into the throat. In fifteen seconds the red litmus-paper was turned blue—this change occurring quite as rapidly and as completely as when the same experiment is performed in the outer atmosphere. In other words, it was not appreciably modified by the breath. Again, litmus-paper moistened with lime-water can be held in the breath for some minutes before its blueness is perceptibly affected by it. This experiment seems to me to show that lime-water spray reaches the fauces and pharynx as lime-water, and does not immediately thereafter cease to be lime-water. When spray thrown into the throat by this method enters the larynx, it does so by being drawn in thither by the inspired breath, which is comparatively free from carbonic acid, and it therefore reaches the walls of the larynx as lime-water, and there continues to be lime-water for a certain length of time.'

"So the red litmus-paper, while dry, was not easily affected by the carbonic acid of the breath? Why should it, when no chemical text-book makes a statement to the contrary? And the red litmus-paper was turned blue by covering it with lime-water—indeed! Litmus-paper owes its very existence and reputation to the fact that it is so very sensitive, and shows the effect of either acid or alkali so readily, and in the most minute quantities. Let us remember that the atomizing apparatus with each pressure sprays about one five-hundredth of a grain of lime; that, therefore, it takes hours to send a grain of lime into the throat; that, however, a membrane has to lie immersed in lime-water for hours before it shows signs of maceration; that lime-water introduced into the trachea, even, through the tracheotomy tube, does not dissolve membranes to any satisfactory degree—though they be only deposited upon, and not (as on the tonsils and parts of the larynx) into the tissue; and though in the trachea the mucus of thousands of glands readily aids in macerating; and though in the opened trachea the lime-water certainly reaches the membrane, which is not so certain in regard to pharyngeal or even laryngeal membranes when you atomize into the mouth and pharynx. And as the doctor relies on experiments, he can add one which he made when he was quite

young. Let him blow into as much as half a pint of lime-water (containing about four grains of lime), and the whole of the lime will be a turbid cloud of carbonate after a very few expirations.

"Here is another experiment: Let the doctor dip blue litmus-paper into moistened carbonate of lime, or a solution of sodium carbonate, or even bicarbonate, and his blue litmus-paper will behave exactly as it does in his patient's throat, to wit, it will remain blue—which is not remarkable at all; and then let him breathe upon the litmus-paper, moistened with calcium carbonate, ever so long, and it will remain blue. Should it not? In his experiments on his patient's throat nothing is proved except that the newly formed calcium carbonate secures the blue color to his litmus-paper for some time. That is all, and requires no proof."

This is a long delayed rejoinder to my "open letter" above referred to, which appeared in your issue of April 3, 1880. As I am not publishing a book at present, I have no other resource than to address to you another "open letter," in the hope that the hospitality of your columns, which I have so often enjoyed, will not be refused to me.

Dr. Jacobi, in his remarks before the Academy of Medicine, had asserted that so rapid is the action of the carbonic acid of the breath upon lime-water spray entering the throat, that "when it does go there it is no longer lime-water," but carbonate of lime, and is "inert, and might as well be replaced by something else." My first experiment conclusively refutes that assertion. Dr. Jacobi says: "So the red litmus-paper, while dry, was not easily affected by the carbonic acid of the breath?" etc. But no such question was raised at all. Will the doctor please state what effect carbonic acid could, under any possible circumstances, be expected to produce upon *red* litmus-paper? But in his next sentence he does exactly state the question at issue, and admits all that the experiment was intended or claimed by me to prove. He says: "And the red litmus-paper was turned blue by *covering it with lime-water*," etc. If it was turned blue almost instantaneously in the pharynx by "covering it with lime-water" from the atomizer, what becomes of the doctor's previous assertion that "when it does go there it is no longer lime-water?" Does the doctor mean to assert that carbonate of lime would produce the same effect upon red litmus-paper? Let him try the experiment.

After this uncordial, but still unconditional surrender to my first proposition (that lime-water reaches the walls of the fauces and pharynx as lime-water) Dr. Jacobi proceeds to attack my second, that "it does not immediately thereafter cease to be lime-water." He adduces the familiar experiment of blowing into lime-water, as ignominiously refuting that assertion. Let us see if it does. Even in this experiment a gill of lime-water becomes increasingly turbid for at least three minutes, although it is kept in violent agitation and the breath is brought rapidly into contact with every atom of lime which it holds in solution. But this does not answer the question as to how much time is required to effect the same change when the breath simply passes over a membrane saturated or covered with lime-water.

Dr. Jacobi says: "The doctor relies on experiments." Verily, I do. What a multitude of unprofitable discussions, not to mention other dire evils, would have been avoided had that reliance and careful performance been more general before rushing into assertion! I will therefore suggest to the doctor still another experiment: Let him take a small bit of Squibb's blue litmus-paper, which, as he correctly informs us, owes its reputation to its extreme sensitiveness to acid in the most minute quantities. Let him first moisten it in *distilled* water and then hold it in his breath. He will find that after two minutes only a very slight change is perceptible; after three minutes the blue has become a venous blue, and after three minutes more it will not have passed beyond a purplish tint. Blue litmus-paper that has been dipped in lime-water will undergo a similar change, only more faintly and several minutes more tardily. But if blue litmus-paper, or blue litmus-paper which has been saturated in lime-water, be dipped into carbonic acid water it becomes bright red in a very few seconds. What does this teach us? Evidently, that when the diluted carbonic acid of the breath passes over a membrane saturated with the solution of a substance for which it has an affinity it does not "instantaneously" penetrate it with complete chemical action, but that this process requires "a certain length of time"—"some minutes." My second proposition is therefore demonstrated.

With regard to the stress which Dr. Jacobi lays upon the smallness of the quantity of lime present in lime-water spray, I remark: 1st, let him spray upon his hand with a Delano atomizer and see how many seconds will be required to make the spot dripping wet; 2d, the same argument would be nearly as effective against most of the therapeutical uses of lime-water, external or internal. It is probable that the profession will hardly consent to its dismissal from the materia medica just yet on any such theoretical ground.

To Dr. Jacobi's argument, from the fact that the maceration of diphtheritic membrane requires hours, it is sufficient answer, that in favorable cases in which this effect is sought the atomizer can be used so frequently as to keep the membrane bathed in lime-water for a considerable portion of the time. Of course this therapeutical agent, like most others, has obvious limitations, some of which I have elsewhere pointed out. But, independently of its solvent action upon membrane, it must not be forgotten that lime-water spray, with the addition, as I use it, of just the proper proportion of carbolic acid (♏ x. in fl. ℥ iv.) is a most agreeable and efficient aid in subduing inflammation.

Dr. Morell Mackenzie says, under the head of solvents ("Diphtheria: its Nature and Treatment," p. 72): "Lime-water is certainly useful when the membrane is not very thick." Dr. Alonzo Clark (MEDICAL RECORD, May 15, 1880, p. 532) says: "The same lime-water to be thrown upon the forming membrane I believe is the most efficacious thing you may have." And similar excellent testimony might be adduced in overwhelming amount did space permit.

Is our list of efficacious remedies in the treatment of diphtheria so numerous that we can afford to discard one which may, in an occasional instance, turn the scale in our favor?

I must beg permission, before concluding, to touch briefly upon a connected topic. I have had the honor to present to the profession, before the New York Academy of Medicine and through your columns,* a method of treatment of diphtheria which has met with wide acceptance. It is a system of precisely defined details, reached through definitely

* Transactions New York Academy of Medicine, 1876, p. 287; New York MEDICAL RECORD, March 18, 1876, p. 199; April 1, 1876, p. 226; January 12, 1878, p. 21; March 27, 1880, p. 383.

stated reasonings from my own accurately related clinical experience. There have been attempts to claim for Dr. Jacobi (who certainly had written before I did) the authorship of my ideas, which attempts have not (to say the least of it) been rebuked by Dr. Jacobi. As the general conclusions upon which we happily agree were original with neither of us, only certain details being strictly "original" with me, and as I have had no disposition to set up any claim to startling originality in reference to anything whatever, nor special objection to any one else's taking credit, if he could, for everything ever said or done about diphtheria from the time of Bretonneau down, and as I have considered that the individuality of my humble contributions to the subject would be sufficiently self-evident to every fairly intelligent reader, I have contented myself with stating the simple truth as to the utter invalidity of the claim, and proving it conclusively by incontestable chronological evidence (*vide* New York Medical Record, February 23, 1878, p. 158).

But I have always insisted that any who should see fit to *test* my method of treatment should test it fairly in all its particulars (making allowance, of course, for such variations as should be required by the exigencies of exceptional cases), that it might stand or fall by its actual merits. If Dr. Jacobi's method of treatment, therefore (so far as he can be said to have ever presented any distinct method), were really (as he has claimed) identical with mine, I should not take the trouble to protest against his going on indefinitely calling my method "our method." But since, when it comes to details, there are wide divergencies in our methods, not only on the important point just now under discussion, but also on others which I consider equally important, and liable in not a few cases to be vitally important, I must enter an objection to their being confounded. Else one who should try one method and find it a failure, might involve the other also in his condemnation, and thenceforth decry (after the manner of some) all local measnres of treatment.

Dr. Jacobi agrees with me that details are "all and everything" in the treatment of diphtheria. It follows that differences of detail should not be overlooked in general resemblances, but that each method of treatment should be judged discriminately by its own results, in order that there may be a "survival of the fittest," and, consequently, of the greatest possible number of patients. Yours, very truly.

C. E. Billington, M.D.

New York, December, 1880.

THE INTRODUCTION OF THE METRIC SYSTEM.

To the Editor of The Medical Record.

Sir—There is a ratio between the unit of the dose of liquid medicines (viz., a minim) and the ordinary dose prescribed (viz., a teaspoonful or 60 min.), which, if applied to the metric system, renders the estimation of doses exceedingly simple and easy, even to one who has long been accustomed to the older system.

Now, as the unit of the dose of solid medicine (viz., a grain) is indicated in precisely the same manner as the minim by the metric system, such doses are estimated with the same facility.

It is evident that to secure a one-minim dose of a drug in a teaspoonful dose of a mixture the ratio of the drug to the menstruum should be 1 to 60.

A 60 gramme (or ʒ ij.) mixture is, I believe, a very ordinary size to prescribe; the following prescription would then contain one minim of the drug in a teaspoonful dose:

	Grammes.
℞. Tr. aconiti	1.00
Aquam ad	60.00
M. S.—Teaspoonful dose.	

and the following would contain 10 minims of the liquid and 15 grammes of the solid drug in a similar dose:

	Grammes.
℞. Tr. digitalis	10.00
Potass. bicarb	15.00
Aquam ad	60.00
M. S.—Teaspoonful dose.	

Thus far, certainly, no mental calculation is required; and from this, as a starting-point, all other doses or other sized mixtures can be computed with the greatest ease and exactness by simple multiplication or division.

An equally simple method for estimating doses for pills, powders, or other dry mixtures is obtained by prescribing in numbers of 15, and multiples or factors thereof, instead of 12, which, I believe, is the *ordinary* number at present.

(I hope this suggestion will not be considered "revolutionary" by those who oppose the introduction of the new system.)

As a gramme contains 15 grains, a pill-mass in which there is one gramme of a certain drug, if divided into 15 pills, will give a grain to each pill. For example: it is desired to make a pill containing 1 gramme extr. colocynth co., ½ gramme extr. nux vomica, ¼ gramme ferri sulph., and ¼ gramme extr. hyoscyamus, and we have the formula as follows:

	Grammes.
℞. Extr. colocynth co	1.00
Extr. nux vom	.50
Ferri sulph	.25
Extr. hyoscyam	.20
M. et in pil. no. xv. divide.	

It will be objected that such a method of calculation mixes up the two systems, and so it does; but this method is recommended only for those who have learned the doses in grains and minims, and to whom it would be almost impossible, certainly impracticable, to forget the old in learning the new.

The change is certainly desirable, and cannot be completely made by this generation. There is precisely the difference in the two methods that there is between reckoning money by the pounds, shillings, and pence of the English and our own dollars and dimes.

I am sure that the practice of a week will satisfy any one as to the advantages of this method, provided he is willing to be convinced that the new system has virtues superior to the old.

These ideas may or may not be original with me; I have never seen or heard them expressed.

C. H. Eames, M D.

East Saginaw, Mich., December 7, 1880.

ACCIDENTS TO OPERATIVES IN COTTON-MILLS.

To the Editor of The Medical Record.

Sir—Operatives in cotton-mills meet with frequent accidents from the machinery.

As this branch of the cotton industry is growing rapidly, it may be instructive to record my experience, extending over a period of two years, with a

mill that employs 2,000 operatives. Within this period several hundred raw operatives have been employed, bringing the number of accidents to a much higher percentage than formerly. Skilled operatives are much less subject to the usual injuries, but even among them there is every year an appreciable percentage of all cases.

The parts coming in contact with the machinery, and consequently most often wounded, are the hands and face. I will briefly describe the most fruitful sources of injury to the hands and face, as these accidents form seventy-five per cent. of all the cases.

Nearly all of the injuries to the hands occur in the card-rooms. On the outside of the cards is a revolving roller, covered with sharp needle-like points, called the "licker-in," from the fact that it conveys the lint cotton into the cards. This roller must be kept free from discolored lint and threads, and is oiled often. While performing this duty the hand comes in close contact with the "teeth" of the cards, and is frequently drawn in and cut.

Another source of accidents is the loom, the fingers being caught between the lathe and beam. Injuries to the face are caused by the shuttle flying out, and by belting and shafts. The finishing shears, too, produce a considerable number of wounds.

All wounds made by the cards are lacerated; by the loom, contused; by the shears, remarkably smooth, clean cuts. The cards furnish the majority of all accidents in this mill, where there have been eighty-five wounds treated in the space of two years. During this period twenty-seven fingers have been amputated, and with few exceptions all of the patients came from the four card-rooms.

The pickers have similar rollers to the cards, but cause only a few injuries, as the hand seldom comes in contact with them.

The treatment of all these wounds has been conducted uniformly on the strict antiseptic plan as laid down by Lister. In only one single incident has there been any complication arising from gangrene, erysipelas, tetanus, etc., nor has it been necessary to perform a re-amputation. In one case three thecal abscesses developed. These facts I mention—not boastfully, nor to prove that I am a blind follower of Lister's method, for I know that many wounds heal well with simple water-dressing, and that many of those that I have treated antiseptically would have recovered by a different mode of treatment—but I simply give results with the antiseptic method. The dressing I have always used is prepared in New York, and consists in the well-known oiled silk, gauze, catgut ligatures, and mackintosh. Operations are performed under a three-per-cent. carbolic spray. In wounds where drainage is necessary the usual drainage-tubes are employed. In short, the entire procedure is followed out as prescribed by Lister. The method as I use it was learned by me at Leipzig, where it was introduced, and is generally carried out by Prof. Thiersch. It would be tedious to give each individual case, or to cumber with details, as much has been written of late, and those elaborate articles on the manner of applying the dressing can be found in text-books and journals. Some minor points I would like to call attention to. Catgut ligatures should be employed when possible. The protective should be entirely covered by the gauze, and it must be impervious to the acid in the gauze. This is done by furnishing the protective silk with a coating of copal varnish. Spray must be used at the operation and at every renewal of the dressing. The dressing must be kept in a close box to prevent evaporation of the acid.

These wounds have all healed up in from six days to two weeks.

From similar accidents to the fingers and hand, three cases have fallen under my observation; all of them were treated by the open method; all three developed tetanus and died.

Repeatedly lacerated fingers and toes that have been brought to me for immediate amputation have been saved. In addition to these wounds in the Eagle and Phœnix Mills, I have treated many others in private practice antiseptically, and with unvarying results. Two cases I saw in consultation in private practice, that were treated by the open method, died respectively from septicæmia and erysipelas. In my practice at the Eagle and Phœnix Mills, in no instance has a modified antiseptic procedure been adopted, but in every case the same strict regard for antiseptic minutiæ has been observed, without speculation as to specially adaptable or non-suitable cases.

Previous to the adoption of the thorough antiseptic method, several hands and arms were amputated in the Eagle and Phœnix Mills, owing to accidental wound complications. Among the number of accidents that I have treated at the Eagle and Phœnix Mills, I will give some of the most striking: Amputation of twenty-seven fingers, and eight toes; treatment of five scalp wounds, three burns of face and arms, two gunshot wounds through the arm, one wound through the hand caused by ram-rod from pistol, one scald, one incision in thigh with dislocation of patella, one splinter through the foot, one laceration of radial artery, one incision in face three inches long and through the cheek with fracture of pons zygomaticum, three incised wounds in one man. This last-mentioned patient received one wound in each arm about one and one-half inches deep and three inches long, about two inches from the head of the humerus; the third wound was in the nape of the neck, extending downward along the spinal column; into it half of the hand was conveniently inserted. All of these wounds were closed with carbolized silk sutures and dressed with antiseptic dressing. At the end of six days union was completed without the slightest suppuration having taken place. Since the introduction of the antiseptic dressing at the Eagle and Phœnix Mills, the results attending its use have been so eminently satisfactory that the authorities of these mills urge its use in every case that falls within their jurisdiction.

S. N. JORDAN, M.D.

COLUMBUS, GA.

DR. C. L. MITCHELL'S NEW INSTRUMENT FOR MEDICATION OF THE DEEP URETHRA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In your journal of December 25, 1880, I see an article by Charles L. Mitchell, of Philadelphia, on "Local Medication of the Deep Urethra," in which he describes what he is pleased to call a *new* instrument and method of making applications to the deeper portions of the urethral canal. I read with pleasure the sound teaching in said article, and agree with its author that local applications to the urethra are often necessary for a successful cure, when injections, either alone or combined with nauseous doses, will utterly fail.

In several articles I have laid great stress on the necessity of local applications, as above cited, and

not exclusively to the *deep-seated* parts, but to any diseased portion of the organ, no matter in what portion it occurs, and whether in the male or female.

I advocated such procedure, among others, in an article on the endoscope, etc. (*American Practitioner*, August, 1871), about ten years ago. Though agreeing perfectly with the principle of Dr. Mitchell, I cannot see, on the other hand, why the doctor calls this a *new* method, and his simple tube a *new* instrument.

For the last thirteen years, if not longer, I have practised local applications to the urethra in various ways. In the "Transactions of the Medical Society of the State of New York for 1870" you will find my article on the endoscope, in which the practice of local application with ocular observation is illustrated. To find a diseased spot of the urethra from the touch alone, by means of a bougie à boule, I have shown in a paper, "Electrolysis in the Treatment of Strictures of the Urethra," published in the "Transactions of the Medical Society of the State of New York for 1874." Soon after I ordered a straight tube of hard rubber for the introduction of urethral bougies *in situ*. These tubes were manufactured and have been sold up to the present time by Messrs. Geo. Tiemann & Co., New York. The same gentlemen made for my use, at about the same time, an instrument which is almost a facsimile of the tube represented in the last edition of your valuable journal as the *new* instrument of Dr. Mitchell.

My instrument consists of a hollow silver tube ten inches long, and of the size of No. 20, French scale. The lower end is slightly curved, in order to reach the deepest portion of the urethra. For the easier introduction of the instrument, a movable plug, runs through this tube. This same plug is also used for propelling the urethral bougies out of the canula into the urethra. For this purpose Dr. Mitchell has only "*an elastic steel stilette*," which is the only difference between the two instruments; but even this can scarcely be called a difference, as I have attached to my instrument also an elastic wire, twisted at the end, corkscrew-like. To this end a cotton-pledget is twisted, dipped into a solution, and carried through the tube, to the diseased portion of the mucous lining. The same wire is also used for cleansing diseased parts. I have, therefore, two applicators, the wire for carrying solutions, and the plug for carrying in solids, *i.e.*, bougies; the first at the same time acting as a cleanser, and the second as a guide for the introduction of the tube. A good illustration of plug and wire can be found in cuts in "Transactions of the Medical Society of the State of New York for 1870," opposite page 121.

Having herewith proven, I believe, that neither the method nor the instrument of Dr. Mitchell is new at this time, I am far from claiming it myself as an original idea, and know that many surgeons have practised the same method at the same time and previous to myself.

I am writing these lines on the spur of the moment, without the aid of a library, but believe the instrument to be so simple that representations of it can be found in old authorities.

Urethral bougies I have used in different forms, and made of the same material Dr. Mitchell enumerates, for the last fifteen years, without claiming any originality myself. The first idea to use gelatin, glycerin, etc., was given me in an article written by a French surgeon, whose name I cannot recall at this moment. Such manufacture has been considerably improved by the French, until the trade was supplied with the elegant articles by Reynal. At the present time we can get good medicated bougies made to order in this country. They are pressed into moulds with great force by a brass machine.

My object in writing this is not to differ with the author of the aforementioned paper; on the contrary, to agree with and to congratulate Dr. Mitchell for having brought to the notice of the profession at large such an important subject as local medication of the deep urethra, and to blame myself not to have written about it ere this. There can be no doubt that Dr. Mitchell has acted in good faith, not knowing that such an instrument has been used before.

ROBERT NEWMAN, M.D.,
Surgeon to Northwestern Dispensary.

NEW YORK, December 27, 1880.

TRACHEOTOMY AND THE TUBE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In your remarks on the sad case of Dr. Wilbur F. Sanford's death from diphtheria, you say that the prompt clearing of a "tracheotomy-tube is very important, but there should be other ways of doing it than by the direct application of the surgeon's mouth . . . . It seems strange that no suitable instrument for such a purpose has been made."

I think several means are at hand. Most important of all is, of course, never to use other than double canulas, which permit the removal of the inner tube and the cleaning of it with a feather, which latter may also be pushed through the outer canula in order to remove obstructions below it. In the second place a pair of forceps, so curved as to be able to be introduced through the whole length of the canula, and even somewhat beyond, is very useful in case of croup membranes blocking up the calibre of the tube, or accumulating below its inferior end. I had one made some years ago by Tiemann & Co.

Finally, for cases where the obstruction is due to fluid accumulating below the canula, there is an old instrument, which at all events will prevent blood and mucus from coming in direct contact with the operator's mouth. It consists of a double necked bottle. To one of the necks is attached a rubber tube leading to an elastic catheter, which is introduced through the canula. When suction is made at the other neck fluids are drawn into the bottle and fall to its bottom. But even the inhalation of the air aspired is likely to be fraught with danger. I think, therefore, that the bottle might be replaced by a Davidson's syringe, which usually is easily obtained. By taking off the plunger and tying the rubber tube air-tight round the catheter, the necessary suction force can be produced by compressing the bulb in the usual way.

Yours respectfully,

H. J. GARRIGUES.

104 WEST FORTY-FIFTH STREET.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 25, 1880, to December 31, 1880.

MEACHAM, F., Capt. and Asst. Surgeon. To report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 275, A. G. O., December 28, 1880.

NEW YORK ACADEMY OF MEDICINE.—At a stated meeting of the Section on Obstetrics and Diseases of Women and Children, held December 23, 1880, Dr. Henry E. Crampton was elected Chairman, and Dr. Alex. S. Hunter Secretary for the ensuing year.

DR. HENRY C. CAFFEY, who for the last ten years has lived in this city, died December 28th, at his residence, No. 315 Madison avenue, at the age of sixty years.

DR. ROBERT NESMITH.—Dispatches from Paris announced the sudden death, on December 28th, of Dr. Robert Nesmith, son of the late John P. Nesmith, of this city. Dr. Nesmith was about forty years of age. He was educated at Columbia College and the College of Physicians and Surgeons, and had been abroad for the last two years. He was a member of the Century Club, and regarded as a very promising member of the medical profession, while his literary abilities were considerable. He was the author of the sketch of the late Dr. Anthon which attracted general attention some years ago. It is conjectured that heart disease was the cause of his sudden death, but the members of the family are not yet informed as to particulars. He leaves a widow and one child.

VIVISECTION AGAIN.—Mr. Bergh opened his winter campaign against vivisection by a free, illustrated lecture on the subject, which he delivered at Association Hall, on the evening of the third inst. The hall was about two-thirds full, part of the audience being medical students. These young gentlemen showed their lack of sympathy with the speaker by applauding the name of every physiologist as it was mentioned. On the whole, however, they behaved very well, and the only approach to disturbance was when the speaker announced his belief in a hell, and that eternal torments were in store for certain physiological professors whose alleged cruelties were dramatically portrayed.

There was nothing in the speaker's remarks deserving the name of argument. The lecture was made up of anecdotes illustrating the intelligence of animals, followed by carefully selected and judiciously mutilated accounts of vivisections. He described some of the vivisections at the Veterinary School at Lyons, and spoke confidently of its professors being eventually consumed with fire and brimstone. He referred, of course, to the "bellish Magendie," and thought Sir Astley Cooper, Bell, Brodie, and Bernard not much better.

He assured his audience that the cruelties practised on the continent were going on, and in this city and state; and he described a vivisection which was performed at one of the colleges in this city. A dog was anæsthetized, and its thoracic and abdominal viscera exposed, in order to show the action of the heart and lungs. This the lecturer considered monstrous.

The burden of Mr. Bergh's remarks was this: animals have feelings and intelligence; vivisection is cruel and useless; therefore, please sign my petition to have it abolished.

The amount of cruelty in vivisection was grossly exaggerated, and the character and humanity of physiologists basely slandered; on the other hand, the usefulness of vivisection in the past, and its necessity for scientific progress were entirely ignored.

THE INTERNATIONAL SANITARY CONFERENCE began its meetings at Washington, on January 3d, and was well attended by representatives of the leading countries of Europe and America, and by representatives from Japan and China. England and Germany will be represented by the Consuls-General of those two countries stationed at New York, and Canada by Dr. Tache, Deputy Minister of Agriculture. France, Austria, Italy, Russia, Turkey, Sweden and Norway, Spain, Portugal, Belgium, Netherlands, Japan, China, Brazil, Mexico, and Chili will be represented by their respective Ministers Resident at Washington.

INSANE ASYLUM MANAGEMENT.—The Wisconsin Insane Asylum has recently been investigated by a Legislative Committee with the result of finding incompetent and extravagant management. The committee recommends a change in the management, the appointment of a paid Board of Trustees, and the entire separation of the medical from the business department of the asylum.

It is at least gratifying to see that the necessity of separating medical from executive management is becoming appreciated.

CRIPPLES IN GERMANY.—The number of deformed, lame, hump-backed people is very great. An English doctor told us he had never seen so many ricketty, ill-kept, and wretched-looking children as in Germany. How can it be otherwise? The mothers are in the fields, and cannot be looking after their babies, mending and making at home, where surely there is always enough to do for one pair of hands. As we drove along, the cripples sat by the roadside tending cows and goats, which must never be allowed to go alone, lest they should stray beyond their owners' narrow frontiers. Carts, with small wheels very far apart, most rudely put together, passed us driven by women.—*Lady Verney, in Contemporary Review.*

DEATH OF DR. DAVID P. SMITH.—Dr. David P. Smith, Professor of Surgery in the Yale Medical School, and one of the most prominent surgeons of the state, died at his residence, in New Haven, on December 26th.

THE WATERS OF THE HOT SPRINGS at Arkansas are said by one of the old physicians of that place, Dr. G. W. Lawrence, to kill consumptives. Dr. L. declares that, having no interest in any cemetery or undertaker's establishment, he does not want people to go there to die. He does assert, however, that these waters are the most valuable adjuncts in the treatment of chronic diseases of the blood, the skin, and the nervous system, and also in uterine and catarrhal affections, and in "true scrofulosis."—*Louisville Med. News.*

PATENT MEDICINES.—In the year ending March, 1880, England paid stamp duties on 16,627,131 packages of patent medicines. The receipts amounted to £135,366.

A FOG AND SMOKE CONFERENCE has been held in London. The object is to devise some way of reducing now the constantly increasing fog and smoke, which threaten eventually to stifle the city. A number of medical men and sanitarians are connected with the movement.

A YOUNG RUSSIAN LADY, a medical student in Paris, recently shot herself. The cause was supposed to be the fear that she could not pass her examinations.

BISHOPS AND DOCTORS.—"I am not ashamed to say I have a son a doctor."—*Speech of the Bishop of Liverpool to medical men.*

> "How kind of the bishop and how patronizing,
> And yet to his *Punch* 'tis a little surprising
> That speaking to medical men there in session
> He dared speak of shame and a noble profession,
> A bishop looks after our souls, but how odd is
> The sneer that's implied at the curers of bodies;
> For surely it would be no hard task to fish up
> A hundred brave doctors as good as the bishop."
>
> —*Punch.*

AN UNHEALTHY SCHOOL BUILDING. — Grammar School No. 2, this city, has been pronounced unhealthy and dangerous on account of the defective plumbing.

NOT TYPHOID FEVER.—The results of sanitary inspections by officers of the Board of Health show that a large number of cases of so-called typhoid fever are in reality only a low form of fever due to debility, bad nourishment, etc. Such cases are particularly frequent on the east side below Second Street.

THE THERMOGRAPH.—Dr. A. Wellington Adams, of Colorado Springs, Col., gives a very elaborate description and makes very strong claims for a new instrument invented by himself and called the Thermograph. It is described in the *Rocky Mountain Medical Review*, for November, 1880. This instrument will, says the author, give a continuous curve denoting the constant febrile condition of the subject. It has already demonstrated a minor heat curve for typhoid fever. It will also give at the same time and on the same strip of paper a sphygmographic and respiratory curve. The instrument is expected to be of great value to meteorological science.

The following is a brief description of its mechanism and principles: A coiled spring is made of two lamellæ of brass and steel, the brass forming the outer part of the coil. This spring is fixed at the centre, but the free end presses gently against the contents of a short vulcanite tube. As the temperature of the apparatus rises the metal coil expands, and the pressure exerted by the free end varies and always corresponds to the temperature. The vulcanite tube is filled with a powder composed of plumbago, gas carbon, and silver, in a finely divided condition. The electrical conductivity of this mixture changes with the pressure to which it is subjected. Wires from an electric battery are connected so that the current passes through the powder, and it will therefore be understood that with the rise and fall of the temperature, and the consequent changes in the pressure of the coil upon the powder, the intensity of the current will vary. It is now only necessary to arrange a means of recording these alterations in the current, and this has been done in a very ingenious manner. A wire helix, of special construction, forms part of the circuit, and into this a soft iron core is passed, free to move up or down. The position of the core is governed by the strength of the current, and as the core rises and falls it communicates motion to an index which records its position continuously upon a moving strip of paper. The battery and the recording part of the instrument are placed in a neat cast iron case, while the coil is enclosed in a German silver case about an inch and a quarter in diameter. To use the thermograph it is only necessary to place the little case in the axilla of the patient, and a continuous record of the temperature is thus obtained. The cost is estimated to be not over $50.

THE TWENTIETH ANNIVERSARY OF THE MEDICO-CHIRURGICAL SOCIETY OF GERMAN PHYSICIANS of this city was celebrated by a dinner at Sieghörtner's, Monday evening, December 20th. Before sitting down to the banquet, the proceedings of a regular meeting were transacted, the matters of most interest being a case of a particle of iron in the vitreous, which was seen on the eighth day by Dr. Brekes, and which the magnet was powerless to remove. The eyeball was enucleated. Following this report was the discussion on the management of the placenta in abortion and at full term, when adherent. The weight of opinion was in favor of the expectant treatment—that is, removing all the portions of placenta easily removable, but applying no violent force to tear off those tightly adherent until constitutional symptoms gave the indication.

The officers of the society for the ensuing year are: *President*, Dr. C. Krog; *Vice-President*, Dr. F. Nordemann; *Treasurer*, Dr. Wm. Guden; *Recording Secretary*, Dr. L. Weiss; *Corresponding Secretary*, Dr. I. Scheider; *Executive Committee*, Drs. Lilienthal, Hackeling, and Kohn; *Librarian*, Dr. I. Glaser.

DEFIBRINATED BLOOD IN RECTAL ALIMENTATION — Dr. Andrew H. Smith, of this city, writes: "I have found recently, by trial in a considerable number of cases, that the disagreeable odor sometimes observed about patients who are using defibrinated blood for rectal alimentation, may be almost or entirely obviated by the addition of a grain or a grain and a half of chloral in solution to each ounce of the blood. There is also this further advantage, that if the chloral is added to the whole quantity of blood when first received, decomposition will be delayed for two or three days longer than without the chloral, and a less frequent supply will be required. When the use of the blood tends to produce constipation, as is often the case, an occasional laxative should be given to prevent possible impaction in the colon."

DEATH AND THE TRACHEOTOMY-TUBE.—The gentleman to whom reference was made in a recent number of the RECORD, and who sacrificed his own life by diphtheria in trying to save that of a patient suffering from the same disease, was Dr. Wilbur F. Sanford, of Greenpoint, N. Y.

REMEDY AGAINST DUPLICATING PRESCRIPTIONS.—Dr. E. T. Blackwell suggests (*Phila. Medical Times*), as a remedy for the above evil, that Congress be appealed to, and that physicians' prescriptions be made copyright. The handwriting of the author and his autograph should be held sufficient to establish his claim to the property in question.

Original Lectures.

SERO-FIBRINOUS PLEURISY.

A Lecture,

By A. L. LOOMIS, M.D.,

PROFESSOR OF PATHOLOGY AND PRACTICE OF MEDICINE IN THE UNIVERSITY MEDICAL COLLEGE, NEW YORK.

(Reported for The Medical Record.)

Part II.

During the stage of effusion, bulging of the intercostal spaces, the displacement of the heart and abdominal viscera, will be easily recognized, and the presence of which will render it almost impossible for you to make a mistake in the diagnosis. But during the stage of absorption and adhesion, when there is no longer bulging of the intercostal spaces, no displacement of the viscera, etc., you have to rest your differential diagnosis almost entirely upon the signs obtained by auscultation. In fibrous induration of the lung there is retraction, and dulness on percussion; the same in the latter stage of pleurisy. In the former there is loss of motion on the affected side; the same in the latter. In the former there is increased vocal fremitus; in the latter vocal fremitus is diminished, so that by vocal fremitus you may be led to a correct diagnosis. Again, upon auscultation in pleurisy at this stage, you will hear feeble respiration at a distance, while in fibrous induration of the lung you will hear bronchial respiration, or distinct tubular breathing. The bronchial breathing which you get in the stage of effusion in pleurisy is distant and diffused, and this disappears during the stage of absorption and adhesion, and you get only feeble respiration, not bronchial in character. But in fibrous induration, or in any form of pneumonia, there will be high pitched bronchial expiration. In phthisis râles will be more or less abundant over the chest, persisting during all stages of the disease, and râles are present in fibrous induration of the lung, but they are not present in pleurisy with retraction, or after the stage of absorption and adhesion.

But suppose the patient have that form of pleurisy which comes on quite suddenly, not gradually, as it usually does, and then the pleural cavity fills with fluid, but you hear distinct bronchial respiration behind: how are you to differentiate between the bronchial breathing in this case and that heard in pneumonia? The bronchial breathing in pneumonia is heard at the bottom of the lung, at the seat of consolidation; that in pleurisy is rarely heard below the scapula, it is usually heard only over the scapula. Then, if there exist any doubt with regard to pleurisy with effusion, do not hesitate to introduce the hypodermic needle. If you find fluid, your diagnosis is positive. But, gentlemen, do not place too much dependence upon the hypodermic needle, for you may sometimes introduce it into the pleural cavity and fail to get fluid even when fluid exists. It seems to me that since the aspirator and the hypodermic needle have come to be used as a means of diagnosis in these cases, physicians are not quite as careful in their appreciation of physical signs as before. The physical signs in sero-fibrinous pleurisy ought always to be sufficient to enable you to make a diagnosis without the exploring-needle. But this instrument is always at hand, and can be used if you wish. There is, however, one condition in which you will find it necessary to use it, in order to reach a positive diagnosis, and that is in cancer of the lung, or rather of the pleura, for primary cancer of the lung is a rare affection.

Almost all cancerous developments filling up the chest cavity commence in the pleura. Cancerous developments usually begin above and extend downward, so that if you see the case early it is not difficult to draw the line of differential diagnosis between this affection and pleurisy, as the physical signs of the latter begin at the bottom of the pleural cavity, those of the former above. If you do not see the case until later, when the cancerous development shall have filled the entire cavity, you will find a bulging of the intercostal spaces, flatness on percussion, absence of respiratory murmur, and all the signs apparently of sero-fibrinous pleurisy, and you will introduce the aspirator needle with the firm belief that you will find fluid. You withdraw it, and find nothing but blood; you plunge it in farther, but still nothing but blood; you introduce it at different places, and nothing yet but blood. Under these circumstances you will begin to suspect that you have something besides fluid in the pleural cavity, and rightly, too. I have seen two or three such cases within a year or two. I was recently asked to see a patient who presented all the physical signs of pleurisy with effusion. I was asked by the physician in attendance, smilingly, for a diagnosis. I answered: "I suppose we have fluid in the pleural cavity." He said that when he first saw the case the flatness existed above, and had gradually extended downward. That, of course, changed my opinion at once, for pleurisy with effusion does not act in that way. I asked if he had aspirated the patient. He said he had; had aspirated him at different points. He wished I would aspirate him also. I did so, and I drew off six ounces of fluid. The doctor looked blank. He could not understand it; but when I aspirated again, and at another place, I could get no fluid. I had accidentally struck a cyst in the first instance. The doctor was right in his diagnosis. The patient had a cancerous development in the pleura which began above and extended downward, and in its later stages it presented all the physical signs of pleurisy with effusion.

When I was a student of medicine a patient presenting similar symptoms to the one just mentioned came under my care in Demilt Dispensary. The diagnosis of subacute pleurisy with effusion was made and the trochar introduced, but it was a dry tap. He afterward went to Bellevue Hospital, and one of the oldest physicians of the hospital made the diagnosis of subacute pleurisy with effusion, and he was again tapped, and with the same result, no fluid was found. He went to three different hospitals, at each one of which the same diagnosis was made, and the same result obtained upon tapping, and finally he came back to Bellevue Hospital and entered my service. I kept close watch of the case from first to last, and had made up my mind some time before his final return to Bellevue Hospital that he had cancer of the lung, and not subacute pleurisy. A post-mortem examination showed that the lung on the affected side was completely infiltrated with cancer. I have spoken of these cases that you may be impressed with the difficulty which sometimes attends the differential diagnosis in such cases.

The *prognosis* in sero-fibrinous pleurisy will depend altogether upon the conditions under which it occurs. If it occur in one who is simply run down

from overwork, or from depressing atmospheric influences, or who has been working under high pressure for a long time, and, being in a debilitated state, takes cold, and has a low grade of inflammation in the pleura, with effusion, complete recovery usually takes place. The prognosis is good. Not alone will absorption of the fluid effusion take place, but entire freedom of respiration will follow. But in those cases where there is a strong hereditary predisposition to phthisis, or where there are already the physical signs of phthisis at the apex of one lung, the prognosis should be very guarded; such cases are very likely to terminate unfavorably. Please understand me. When I speak of a strong hereditary predisposition to phthisis I refer to persons born of parents who had developed phthisis at the time of their birth. It is possible for a mother who died of phthisis to have given birth to a vigorous child at some time in her life, but if a person born of such a mother, at the time when she had phthisis developed, shall come to you for advice, complaining of shortness of breath, and you find fluid in the pleural cavity, you have reason to suspect that there is a predisposition to phthisical developments; that the inflammation which is giving rise to this condition is a tubercular inflammation, and although the fluid may be absorbed and the surfaces of the pleura come together again, the chances for recovery are small. The clinical connection between this form of pleurisy and phthisis is a very close one.

If the fluid shall remain in the pleural cavity a long time, compressing the lung and interfering with its circulation, a catarrhal pneumonia is likely to develop, or, at least, lobular consolidation which shall lead to phthisis. Again, there is a form of phthisis in which the fibrous indurations are liable to begin at the pleura and gradually extend into the lung-tissue, sometimes having for its origin a sero-fibrinous pleurisy.

Thus you see, gentlemen, it is by no means a trivial matter to have a sero-fibrinous pleurisy. Do not, then, deceive your patients regarding it. Do not tell them it is nothing but a pleurisy, as if it were a matter of no consequence. Tell them that their disease is serious in its nature, that they may completely recover, but that it is attended by certain dangers. The more I see of phthisis the more am I convinced that a large number of cases commence with this form of pleurisy; that the phthisical developments which occur after a pleurisy really have their origin in a pleuritic inflammation which has given rise to the physical signs of fluid effusion into the pleural cavity.

Treatment.—The main thing to be accomplished in the treatment of this disease is to remove as rapidly as possible the fluid effusion which is distending the pleural cavity. It is important that while you are accomplishing this, you shall sustain by every possible means the vital powers of the patient.

The means which have been proposed, and which are used largely for the removal of the fluid, are included under the head of hydragogue cathartics, diuretics, and diaphoretics. It has also been the custom to apply blisters to the surface of the chest. There are few at the present time who will resort to general or local bloodletting in the treatment of this form of pleurisy.

The objections to general or local bloodletting are, that the patient is in a debilitated condition at the time of the occurrence of the pleurisy. It is, in the majority of instances, as I stated to you in connection with its etiology, a secondary affection, or it is especially likely to develop in those who have a tubercular or a phthisical diathesis. This class of individuals never bear depletion well, and it is for this reason that some years ago it occurred to me that hydragogue cathartics and diuretics were prejudicial rather than beneficial in this disease; that while they did not positively remove the fluid effusion rapidly, they did diminish the vital powers of the patient. That they rather prevented the absorption of the fluid than aided in its removal.

The theory upon which the administration of hydragogue cathartics and diuretics in the treatment of this disease is based is, that they diminish the fluid constituents of the blood, and cause the absorbents to seize upon fluid existing abnormally in any portion of the body, whether it be in the pleural cavity, in the abdominal cavity, in the cellular tissue. That the rapid disappearance of fluid from cavities and the cellular tissue of the surface, in general dropsy, will follow the administration of diuretics and hydragogue cathartics, there can be no question, but you must remember that in such cases the effusions are not of an inflammatory origin; they are not the products of inflammation. They are simply the watery elements of the blood which have passed through the walls of the capillary vessels as a result of interference with the circulation. For instance, tie a string around your arm and compress the veins to a certain degree, so as to interfere with the return circulation, and you will have œdema. Now, in sero-fibrinous pleurisy, or in any form of pleurisy, such is not the cause of the effusion; the cause is an inflammation. Moreover, the effusion is not simple serum; it is sero-albuminous and sero-fibrinous. We have no evidence that the capillary vessels and the absorbents have the power to remove inflammatory products simply because the blood has been deprived of its fluid constituents by the action of hydragogue cathartics and diuretics. There is an entirely different condition in the two cases.

Again, when describing the pathological condition of this form of pleurisy I said that when the pleural cavity is distended with fluid, the capillary vessels on the surface of the lung, and in the pleural and subpleural tissue, are compressed, and cannot absorb fluid. So long as they remain compressed, all depurative means—means which are employed for removing fluid from the system in dropsy—will have no effect. Another objection to the use of these means is, that there is a fibrinous deposit upon the surfaces of the pleura which interferes with absorption of the fluid by the absorbent and capillary vessels, and the thicker this deposit the more it interferes with absorption.

Still another objection to the use of these depurative means is, that absorption of all inflammatory products goes on most rapidly when the vital powers are at their highest point. In a man debilitated and broken down the removal of inflammatory products takes place very slowly, if at all, it matters not what the inflammatory products may be; but when the nutritive powers are carried to their highest point, and the waste and repair of the system is rapid, absorption of inflammatory products will take place most rapidly.

It was the custom when I entered the profession, in the treatment of subacute pleurisy, to apply a blister on the front of the chest, and after three days to apply another in the axillary space, and after three days more another behind, and by that time the surface had nearly healed in front and the ground was gone over again. Now, gentlemen, you undertake to

treat a young, delicate, sensitive female in that way, and you will find she will not bear it; she cannot bear it. I remember the first time I treated a case of subacute pleurisy without a blister. I did it because my patient would not be blistered, and I found that the fluid in her pleural cavity disappeared as rapidly if not more rapidly than I was accustomed to see fluid effusions disappear. That led me to try its treatment without the blister, and I went on trying, and am trying it still, and I find that I get rid of the serous effusion just as rapidly as those who use the blisters. I do not say that there are not cases in which there is a low grade of inflammatory action, accompanied by a good deal of pain, where blisters may be of service. Under those circumstances they afford relief to the pain, but I do not believe that they remove or assist in removing the fluid effusion.

Then, gentlemen, if a debilitated state stands in the way of absorption of the fluid effusion, why deplete your patient with hydragogue catharties? But you say you do not deplete him. I would like to know if depriving the blood of its fluid elements by way of the bowels is not as much depletion as to abstract blood from the arm. If you do not think it debilitates one to take a hydragogue cathartic, go home to-night and take a grain of elaterium, and see if you come to lectures to-morrow. And yet you force these patients to take it not only once, but twice; they have four or five watery discharges, and each time they grow paler and weaker. But you do more than that. No hydragogue cathartic can be introduced into the stomach without disturbing the digestion. I wish doctors would stop and think once in a while, when they are putting these awful doses into the stomach, what that stomach was made for, how it revolts at it, how the patient loses appetite, how his digestion is interfered with, and with it his nutrition. You are really doing harm, because you are interfering with the very processes by which you are to remove this inflammatory exudation.

The same remarks apply, though in a less degree, to diuretics. They will deplete one, though not to the same extent, and they interfere to some extent with the nutritive processes. If you take the acetate of potash, or the nitrate, which, perhaps, is the most vigorous, for forty-eight hours, so as to get its full effects as a diuretic, the flow of the urine will be increased abnormally, and the next day you will feel weak and debilitated. I do not call digitalis, strictly speaking, a diuretic. It increases the flow of urine, but it does so by regulating the circulation.

You ask, how are we to remove this fluid from the pleural cavity, for it is all important that it be removed as soon as possible. Here arises the question of drawing off the fluid by mechanical means. In other words, shall you perform paracentesis thoracis in this form of pleurisy? You will find the profession divided in opinion with regard to its propriety. Some say there is danger of air entering the pleural cavity during the operation, and setting up in the place of the sero-fibrinous inflammation a sero-purulent one, and thus jeopardize the life of the patient. Others say that if you allow the fluid to remain in the pleural cavity, thickening of the pleura takes place by the process I have already described, and that there is danger of a different kind of inflammatory process being established. There can be no question but that if the fluid effusion remain too long in the pleural cavity it will cause by its very presence a change in the inflammatory process as certainly as the presence of air in the pleural cavity.

You see, gentlemen, the argument, theoretically, is strong on both sides. If by aspirating you shall change a serous into a suppurative pleurisy, you certainly should not resort to it; and if by allowing the fluid to remain in the pleural cavity you shall have a sero-fibrinous pleurisy changed into suppurative pleurisy, it should be removed at all hazards. I would not take the extreme of either side. There is a middle ground upon which you may stand.

If the pleural cavity is filled, or almost filled, with fluid, and shall continue so without diminishing, but rather increasing from day to day, compression of the lung having already taken place, do not hesitate to aspirate. It is impossible for air to enter the pleural cavity if you use an aspirator. If, when called to a patient, you find the chest distended with fluid, the heart and liver pushed out of position, great dyspnœa, the result of the fluid distention, then you know the condition of the serous and subserous vessels is such that absorption of the fluid cannot take place, and without waiting you should aspirate.

I will give you a few suggestions regarding the method of aspirating. Let the arm on the affected side be brought across the chest so as to render the tissues over the affected side moderately tense. In the sixth intercostal space, at the junction of the axillary and infra-scapular regions, introduce the aspirating needle. Introduce it at least two inches, and allow the fluid to flow as long as the patient does not evince any uncomfortable sensation. As soon as he begins to feel a sense of constriction about the chest, stop. I care not whether you have drawn off four ounces or twenty, stop. Why? Because it shows that the lung is not expanding sufficiently to fill the space that has been occupied by fluid.

If the fluid has remained in the pleural cavity only a short time, the thickening of the pleura will be slight, and the lung will expand readily. If the pulmonary pleura be not much involved, the lung will expand readily, and you may be able to draw off all the fluid at one time without any inconvenience to your patient. The chances for that patient's recovery are much better than those of one in whose pleural cavity the fluid has remained for a long time, and much thickening of the pleura has taken place, whose lung expands very slowly, so that only a small quantity of fluid can be withdrawn at a time. In this latter patient's case, when he begins to feel that sense of constriction on withdrawing fluid from his pleural cavity, and begins to catch his breath, wait a day or two, and then aspirate again. You will find that the next time you will be able to draw off a little more fluid than at the first operation. After another day or two repeat the operation, and so continue to do until all the fluid shall be removed from the pleural cavity. Now, gentlemen, I am convinced that by the judicious management of the aspirator you will be able to save a large proportion of your cases from the dangers which surround them when fluid is allowed to remain in the pleural cavity a long time.

Is there nothing else to be done? Yes, it is most important to increase the nutrition of the patient, so that after you have removed the fluid, changes shall take place in the plastic material which shall facilitate its absorption. Of all the drugs that have any power in this direction, I believe iron is best, and of all the preparations of iron, I think the syrup of the iodide of iron is the best. But do not give it in five- or in ten-drop doses. If you want any good effects from it, give it in large doses, at least a teaspoonful every four hours.

Give nutrition in a concentrated form; keep the patient in an even temperature. The surface of the body must not be exposed to changes of temperature. This class of patients must not be exhausted by prolonged mental or physical labor; they must remain quiet, in rooms of an even temperature, in bed most of the time, until the fluid shall have disappeared. When their strength will permit, they may ride out, well protected, in the fresh air. It is wonderful how the moderate use of stimulants helps this class of patients when they begin to recover. Their nutrition may often be increased very much by champagne with their meals. I never speak of this but I think of a reverend gentleman, about fifty years of age, who once came under my observation. He unfortunately attempted to carry on his work for a considerable time after his pleurisy had developed. Finally, the pleural cavity became filled with fluid, he suffered from shortness of breath, and was compelled to cease his work and call his physician. His physician had been brought up in the school of hydragogue cathartics, diuretics, and diaphoretics, and commenced on his already weak, feeble, anæmic patient by giving him elaterium in pretty full doses, purging him freely, and following that up with diuretics; and he would occasionally add to that a diaphoretic hot-air bath. He thought, moreover, it was quite important to put his patient upon a low diet. The result was, the reverend gentleman got into bed and was unable to get up. He began to have profuse perspirations. Under these circumstances he soon passed into a very critical condition. I saw him about this time, and proposed that he should stop hydragogue cathartics, diuretics, and diaphoretics, and be put upon the plan of treatment which I have proposed to you, and, as soon as his condition was slightly improved, to aspirate his chest. It was not very many days before the patient was able to be out of bed. He began to assume a more cheerful aspect. He took stimulants very kindly, taking a quart of champagne each day; in fact, he was not restricted in its use. Within a week I aspirated him a second time, and drew off about a quart of fluid. I aspirated him, I think, three times. From the first absorption his improvement was rapid. He entirely recovered, and is doing useful work to-day. I simply mention this case to illustrate what a marked change for the better takes place in some of these patients under this plan of treatment, after the depurative plan has been thoroughly tested.

Of course, rest from labor, a change of climate to one of an even temperature and high altitude is important during the period of convalescence. Remember, also, that after the fluid has disappeared you have work to do still. The lung is bound down by the pleuritic thickenings and adhesions, and it is important that the patient shall be subjected to systematic gymnastic exercises, in order that the lung may be frequently inflated to its utmost limit.

Dr. Charles McDermont, formerly Surgeon-General of Ohio, and one of the most prominent surgeons in the Army during the war, died at Dayton, O., January 7th, from rheumatic troubles contracted during the war.

The New York State Board of Health has sent in its annual report to the legislature. This report shows that the Board has already done excellent work, particularly in fighting small-pox. A review of the document will be given later.

Original Communications.

CHLORAL HYDRATE.

By H. H. KANE, M.D.,
NEW YORK.

CHLORAL IN SIMPLE INSOMNIA AND THE INSOMNIA OF DELIRIUM TREMENS AND INSANITY.

Part II.

Dr. Earle prefers giving the drug in small doses, often repeated, if necessary, to administering it in one or two large doses.

That drunkards will often bear very large doses of chloral without the production of sleep is seen by the following,[46] as also by several cases related in my article on poisoning.

"In connection with the recent inquest at Weymouth, I find some speculation as to the amount of chloral hydrate that can be taken with impunity, a case being mentioned where one hundred and sixty-five grains caused no ill-effects.

"I was called one evening to a gentleman of extremely intemperate habits, who had been in the habit of drinking as much as three pints of whiskey *per diem* for a month and even six weeks at a stretch. When I arrived at the house, I was informed that he had ordered a bottle of medicine from the druggist's and had drunk the whole of it. On my seeing the patient, he exclaimed, 'I say, Pitts, Pitts, Pitts, I had, had no five, five, five bobs, bobs left to buy, buy whiskey, whiskey with' (every word being repeated three or four times over); 'so I thought I would write a prescription that would have the same effect, if taken, as the spirit.' The following was the prescription:

℞. Chloral hydrat..... gr. cclx.
Potassii bromidi..... ʒ ij.
Spir. chloroform..... ʒ iss.
Aquæ camph..... ad. ʒ x.
Two tablespoonfuls every four hours.

"The whole of this he had taken at one dose some hours previously. I watched the case until I had the satisfaction of seeing the gentleman become more rational and the peculiarities of speech pass gradually away.

"Not knowing any antidote for chloral, I procured him a bottle of whiskey, under the idea that syncope was the immediate cause of death in cases of fatal poisoning with that drug. This he consumed in the course of the night, and in the morning seemed to be all right.

"The chloral did not cause deep sleep or insensibility, but only a stupid maudlin condition, in which he rambled incoherently about different past events, with occasional short naps, from which he was easily roused. His pupils were natural. The only other symptom I noticed was an apparent loss of muscular power; he seemed to have lost, to some extent, his power of grasping firmly any article.

"Henry Y. Pitts, L.R.C.P., Lond., Tue Brook."

The following case shows that chloral may be used after morphia and *vice versa* in many cases without apparent ill-effect. I must still maintain, however, that from the evidence I have found in collecting statistics for my book on "Morphia," and that which I have given in one of my earlier articles upon this

[46] British Med. Journal, Nov. 17, 1877.

subject, that *in some cases* the practice leads to a fatal result.

J. Farrar, of Edinburg, failing in a severe case of delirium tremens, after two or three days of treatment with opiates, resorted to chloral hydrate as follows: at 5.10 A.M., thirty grains; a like quantity half an hour later. At 6 A.M. a hypodermic dose of one-half grain of morphia. At 6.10, forty grains of chloral were given. At 6.25, two-thirds of a grain of morphia was injected, and at 6.55 the patient was asleep, and so remained for eight hours. Recovery followed at once.

In another case, in which digitalis, morphia, etc., had been ineffectual, chloral was resorted to in doses repeated every ten minutes until one hundred and sixty grains had been taken. Seven hours' sleep then took place, and was followed by recovery.

During the first two doses the patient was more excited and garrulous—indeed *intoxicated*—but this soon gave way to thick speech, inarticulate mumblings, and then sleep.—*Br. Med. Jour.*

Dr. A. P. Hayne,[47] of the "Home of Inebriates," San Francisco, Cal., says:

"In all forms of the acute variety there is no combination which, as the result of an experience of many years, can be compared to that of chloral hydrate and one or other of the bromides—especially the bromide of potassium. In doses of twenty or thirty grains of the former, with thirty or forty of the latter, given at proper intervals, either with or without a small quantity of spirit, or ale and porter, it is far superior to any other combination we have ever tried. The second or third dose seldom fails, in the majority of cases, to fulfil the main object of our endeavors, viz.: to tranquillize nervous excitement, quiet the mental agitation, and produce sleep.

"In the selection of the former of these medicines (chloral hydrate) it is highly important to use none but the best article. We always use the imported, generally the *German*, but the English and French are, perhaps, equally good. The American is decidedly inferior and often impure. It should be clear, semi-opaque, and crystalline, with a strong, pungent odor of chloroform, and perfectly white.

"It is also an important point that both of these remedies should be given in full doses, otherwise we may be disappointed in their action, either singly or in combination.

"Occasionally we will meet with patients who will resist very large doses, and in these we sometimes combine one-eighth to one-quarter grain of morphine with each alternate dose.

"In an experience of many years, we have generally found the simple plan thus outlined answer all purposes; and while in some instances we have been compelled by the urgency of the case to push these remedies to an apparently alarming extent, sometimes as high as two hundred to two hundred and fifty grains of chloral hydrate in twenty-four hours, we have never seen a fatal result which could be attributed to an overdose of that much abused but invaluable remedy.

That sudden deaths do sometimes occur in violent attacks of acute alcoholism, in all its forms, is a well-known fact; but in the vast majority of these the post-mortem examinations have revealed the true cause of death, and the explanation is rendered conclusive by the presence of serous effusions, cerebral hemorrhage, or embolism.

"Besides the effects of the chloral-bromide combination which we have just noticed, there is another advantage which the former remedy possesses in stimulating the appetite and enabling the stomach to retain nourishment. It also checks the profuse diaphoresis, controls the delirium, equalizes the cerebral circulation, and is the most certain of all hypnotics."

Anstie,[48] in a review of Mr. Croft's work on "Delirium Tremens in Surgical Cases," says: "The great omission is that he says nothing of chloral hydrate, a medicine which plays so important a part, nowadays, in the treatment of delirium tremens, that its discovery may be said to have inaugurated a new era therein. Chloral need not be given to decided narcotism (a state which is most undesirable in delirium tremens, as it is impossible to say what the issue of it will be), but it *is* capable in many cases of producing simple sleep, and that at an early stage, when scarcely any other drug will have the slightest efficacy in that direction; even bromides will not do so, save in comparatively rare cases, at so early a period."

A careful study of the deaths from chloral in alcoholic patients, given in my last articles (RECORD, December 25, 1880, and Jan. 1, 1881), with contraindications, etc., will bear careful study. The cases are too numerous for repetition here.

J. Milner Fothergill,[49] in the course of an article entitled "The Management of Delirium," says: "If there be considerable vascular excitement and heat of head, opiates are inadmissable. Chloral hydrate in fifteen-grain doses, repeated at hourly intervals, until a drachm be given, is a much more suitable agent, as it exercises a very decided effect upon the vascular system, as well as upon the nerve-centres; or bromide of potassium may be exhibited with advantage. One point must be remembered, and it is this: in the typhoid state, when the tongue is covered with a dark fur of dead epithelial scales, a similar layer of effete cells lines the intestinal canal, and medicines given by the mouth are of little avail, because they are not absorbed. Subcutaneous injections of chloral hydrate of a strength of ten grains to the ounce—in order not to cause severe local disturbance, as stronger solutions are prone to do—will often prove of decided service."

Panas[50] says that in two years experimenting at the Hôpital St. Louis, he has found chloral hydrate an exceedingly valuable agent in the treatment of acute traumatic delirium, especially in alcoholics. In the sub-delirium of surgical septicæmia, he has found it to be of but little use, having had much better results from opium.

INSANITY.

On the first introduction of chloral hydrate as a therapeutic agent it found much favor in the eyes of those who had the medical care of the insane. As time has passed and experience in this field has accumulated, the tide of opinion seems to have set directly against its use, save in certain cases and under certain conditions. I had hoped to have a more complete summary of the views of superintendents and medical attendants of insane asylums than is here presented, but many of the gentlemen to whom I wrote failed to answer, and I am obliged to be content with what I have. This, I am sorry to say, has been the case with reference to many diseases, where the opinions of the parties written to would have been of especial value as coming from specialists. With all due charity, I lay it more at

[47] Alcoholism, etc., op. cit., p. 17.

the door of carelessness and overwork than to lazy apathy and discourtesy.

I shall first give the testimony of those favoring the use of this drug in insanity, and then that of those who object to it.

Couyba[51] was one of the first to employ it in this class of affections, and for calming excitement and producing sleep he seems to have found it eminently satisfactory. He gives a number of cases that progressed favorably under its influence, the symptoms of violence having been alleviated by it in some cases after other remedies had failed.

Dr. Johann Wirtinger,[52] Chief Physician to Vienna Hospital, Ybbs on Danube, Lower Austria, who had eighty-one epileptics and three hundred and twenty insane patients in the wards of a general hospital during last year, found great benefit from chloral at night in the psychical excitement of lunatics and epileptics.

Dr. McIntosh,[53] of the Royal Glasgow Asylum, has used chloral in a number of cases of insanity with varying results. Melancholics say that when it does not cause sleep it slightly intoxicates them. In acute mania, and especially cases of recurrent mania, it failed in many cases to arrest the paroxysms. He speaks highly of it, however, saying it is our best hypnotic.

Dr. John Barclay[54] has found chloral an excellent hypnotic in the insomnia of insanity, also commends it in delirium tremens and epilepsy.

Dr. James M. Keniston,[55] of the Butler Hospital for the Insane, Providence, R. I., gives a number of cases of insanity where chloral acted in the happiest manner. In one case there seemed to be a cumulative action after one hundred and twenty grains in three hours' time. Also relates a number of cases of delirium tremens where it had the same good effect.

Dr. Clouston,[56] Medical Superintendent of the Cumberland and Westmoreland Asylum, has used chloral in forty cases (dose, ten to eighty grains) for procuring sleep, calming nervous irritability, subduing maniacal fury, allaying extreme depression of mind, arresting an attack of mania, and in neuralgia and chorea, with most excellent success. In some cases the temperature was reduced, in others not. Reduction of temperature is a great benefit in acute mania, when the fever destroys the tissues.

Henry Meymott[57] has used chloral with marked benefit in a case of epileptic mania.

Dr. J. E. Bowers[58] advises small doses of chloral, often repeated, in melancholia with insomnia, where the patient is himself anxious for something to procure sleep.

Dr. Antoine Haller[59] states that he has used chloral as an hypnotic in lunatics with marked success. He conducted a series of experiments aiming to show the relative value of chloral, opium, and morphine. He found the best results were obtained with chloral, giving it in some cases for a long time without any bad effects. The quantity of urine was increased. He noticed the peculiarity, that in patients who were constipated the calming effect of the chloral was lessened.

Kjelberry,[60] of Upsal, Sweden, advises the use of chloral:

First.—In all cases of melancholia with sleeplessness; in excitement, hallucinations, and suicidal tendencies.

Second.—In simple melancholia, where natural sleep lasts less than four hours.

Third.—In acute mania, when a new crisis of agitation is impending.

If not borne well by the stomach he gives it by the rectum in the form of a clyster.

In acute mania, at the end of the paroxysms, when sleep has not yet set in, and in chronic mania, when excitement lasts too long, and when dementia is feared, he gives a combination of chloral and morphia.

An interesting series of experiments has been made by Dr. John A. Campbell,[61] of Garland Asylum, Carlisle. He selected fourteen patients on whom to try the relative sedative effects on maniacal excitement of hyoscyamus, bromide of potassium, and chloral. To these patients he gave each of the medicines forty-six times, using the drugs in gradually increasing doses. He concludes as follows: 1st, that both chloral and tinct. hyoscyamus are sure sedatives to maniacal excitement; 2d, that of these two medicines chloral is the most certain sleep-producer; 3d, that chloral acts more quickly than tincture of hyoscyamus; 4th, that though bromide of potassium in such doses is a sedative to maniacal excitement and to a certain extent hypnotic, yet it is not a sufficiently powerful sedative to allay intense excitement, or an hypnotic to compel sleep where great insomnia exists; 5th, that a two-drachm dose of tincture of hyoscyamus is not quite equivalent to thirty grains of hydrate of chloral. Two and a half drachms as near an equivalent as possible. He thinks bromide of potassium is only useful when the excitement or insomnia is of a slight character.

Tuke,[62] basing his conclusions on the study of some patients in the Fife and Kenross Asylums, finds chloral a most reliable hypnotic, its reliability constituting its superiority over other narcotics. One was a case of acute alcoholic mania, two asthenic insanity, symptomatized by melancholia, and one of climacteric insanity with melancholic symptoms.

In one case Tuke[63] found that the use of the drug was followed by considerable mental disturbance.

Crawford[64] speaks highly of the good effects of chloral in a case of acute mania.

Thornley[65] says that he has used it nightly with insane patients for from six months to two years, without noting any ill effects.

Schlangenhausen, of Hall, Tyrol, writes me: "In all cases of exaltation, when the insane are laboring under excitement caused by hallucination and fanatical ideas, in cases of maniacal excitement of the mad and paralytics, for hysterical and epileptic patients and for delirium potatorum, mostly with good effect. The subjects become sleepy one or two hours after taking medicine, the 'sopor' lasting from four to six hours, after a dose of from two to four grammes. In melancholia it often failed."

Dr. Wm. MacLeod,[66] Deputy Inspector General of Hospitals and Fleets, Royal Navy Hospital, Great Yarmouth, sums up an interesting article on the use of chloral in insanity as follows:

"*First.*—That in paralysis of the insane chloral acts as an excellent hypnotic by night and soothing agent by day.

[51] Bull. gén. de thérap., 1870, p. 151.
[52] By letter.
[53] Report of Royal Glasgow Asylum: Edinb. Med. Jour., Oct., 1871.

[65] Lancet, Dec. 18, 1875.
[66] Practitioner, 1870, p. 65.

"*Second.*—That under its influence patients are freed from destructive habits, and gain in weight and strength.

"*Third.*—A small dose continued for days (ninety-five) gave no bad symptoms.

"*Fourth.*—The condition of the bowels and bladder improve.

"*Fifth.*—Patients suffering abnormal sensations derive much benefit from it.

"*Sixth.*—The appetite increases and food is not refused.

"*Seventh.*—It has cut short, in patients thus affected, hallucinations of hearing with suicidal tendency.

"*Eighth.*—Those with the same affection, made noisy by sensation, are calmed by it.

"*Ninth.*—The desire to maim and mutilate themselves periodically, passes away.

"*Tenth.*—In patients suffering from voices which they know depend on morbid sensation but little benefit is derived.

"*Eleventh.*—In certain cases of melancholia there was decided benefit.

"*Twelfth.*—In a similar case, with extreme depression, it had no good effect save to heal a supposed abrasion of the stomach.

"*Thirteenth.*—The greater the disorganization of the brain and cord (as judged by symptoms, especially thermometrical observations) the sooner does the system come under the influence of chloral."

Dr. Wm. A. Hammond [67] has used it in acute mania with success, as has, also, Dr. C. R. Cullen,[68] of Richmond, Va., both by the mouth and rectum in hysterical mania and similar cases.

In puerperal mania excellent results are reported by Webster,[69] Tuke,[70] Teller,[71] Hupp,[72] and many others.

Dr. Henry Maudsley, of England, kindly writes me: "The worst case of puerperal mania I ever saw, was taking 120 grains of chloral daily, in three doses. She began to recover a few days after the chloral was stopped. I have known one case of puerperal mania, in a strong, healthy woman, where death was produced by chloral. Dose after dose (I know not how much) had been given to smother the excitement, and when I saw her she was insensible, pale, cold, breathing slowly and slightly stertorously, with scarcely perceptible pulse. She died soon after."

The danger of pushing chloral to extremes in this as in any other disease is undoubted, and the practice unjustifiable. That it sometimes acts well in a condition of almost collapse is undoubted, as will be seen from the following case.

Dr. Alex. Max Adams [73] reports the case of a delicate female who, four days after the delivery of her first child, was attacked with acute ungovernable puerperal mania. Bromide of potassium, and opium in large doses, failed to give relief. Forty grains of chloral were given at a time when the pulse was scarcely perceptible and the extremities cold. In five minutes after taking the chloral she became calm and conscious. This was followed by profound, shading off into natural sleep. As the attacks recurred they were met with from forty- to sixty-grain doses of chloral until a cure was effected.

Playfair [74] states that puerperal mania has been averted by the use of this drug.

As against the free use of chloral in insanity we have the following opinions:

Dr. Henry Maudsley [75] says: "I use chloral in melancholia, seldom in mania, and then only when subacute, as an occasional thing. I believe it prolongs mania and makes it worse, but I don't know that it causes it."

In a case of tetanus in a boy aged fourteen years, reported by Dr. J. B. Carruthers,[76] Edinburg, where 1140 grains of chloral were taken in sixteen days, all manner of delusions ensued. It is but fair to state that twice as much bromide of potassium was taken.

Dr. Rhys. Williams [77] says that he has used chloral in all forms of insanity, and in no case had good resulted from its use.

Dr. Samuel Clark,[78] Med. Supt. of the Toronto Asylum, says that opium and its salts, and chloral hydrate, are but sparingly used in that asylum.

Dr. W. G. Metcalf, Med. Supt. Asylum for the Insane, Kingston, Ontario, writes me: "We use chloral very sparingly, and consequently our experience of the drug will be of but little value." When used at all he employs it as an hypnotic.

Dr. G. A. Shurtleff, Med. Supt. State Insane Asylum, Stockton, California, writes:

"In the wards of this asylum, where chloral has been given most freely to procure sleep and quietude at night, the patients taking it were found to be more disturbed and troublesome than usual the following day, and uniformly so when the practice was continued without interruption for several weeks. In these cases the drug was given at night only. For some time its use has been much restricted in this institution; and I have come to the conclusion that, on the whole, a faithful care of the insane by their attendants is more easily and agreeably performed without than with the general and prolonged employment of chloral, especially as regards the chronic classes."

Dr. J. Hawkes,[79] Med. Supt. Middlesex Co. Asylum, England, says:

"In cases of general paralysis accompanying mania, in rather elderly persons with feeble circulation and impaired nutrition, the use of chloral is occasionally attended by adverse symptoms. The most usual effect seems to be an increased congestion of the ganglionic centres, little abatement of restlessness, gradual failure of strength, and a corresponding advance of paralytic symptoms."

Dr. George H. Savage [80] (Guy's Hospital Reports, 1878), of the Bethlehem Asylum, thinks that chloral has, all things considered, done as much harm as good. He finds it useful in epileptic mania, in cases due to excess of alcohol, and in puerperal cases. In wildly maniacal and erratic patients he gives it in from ten to thirty-grain doses, rubbed up with an equal quantity of camphor, in syrup. He found alarming symptoms follow, however, in one case, after twenty grains of the mixture had been taken.

Dr. D. B. Simmons,[81] of Yokohama, Japan, from studying the symptoms in a case of poisoning from two drachms of camphor-chloral,[82] decided to try it in a case of acute periodical mania, with excellent success, it succeeding after morphia, chloral, hyoscyamus, and other drugs had failed. The dose was thirty-five

[82] Chloral and gum camphor, when rubbed up together, form a thick syrupy mass.

drops. He claims better results from the combination than could be had from equal or double quantities of either drug used alone. The mixture is worthy of trial. Dr. Eugene Wittich,[83] of Berlin, speaks very highly of the hypnotic powers of camphor used subcutaneously in the dose of fifteen grains in the insomnia of insanity. He dissolves it in almond oil, uses a large canula, and claims that there is neither pain, inflammation, nor abscess. The combination of two such powerful hypnotics should certainly give us a good result in this class of diseases.

Dr. J. A. Campbell, of the Garland Asylum, Carlisle, writes[84] concerning the treatment of excitement by sedatives or otherwise. He has seen instances of an error not unknown to us, chargeable usually to physicians in general practice. The mistake is occasionally made of trying to quell an outbreak of insane excitement by the use of large quantities of ether, chloral, bromide of potassium, opium, or other narcotics, given day and night, without much pains to enforce proper nourishment. This management, if pushed to extremes, may lead to dementia, or death by exhaustion.

Dr. Campbell says that if sleep can be produced at night the patient does better without sedatives by day; chloral, though an efficient sleep producer, is dangerous from its depressant action on the heart, and should not be used in frequent or repeated doses by day. In the excitement of general paralysis sedatives should not be given which, like the bromides, impair still further the powers of locomotion and deglutition. In the few cases where he has been obliged to resort to continuous sedation, he has found the bromides alone almost useless, but in combination with cannabis indica, hyoscyamus, valerian, or even opium, the bromide acts as a drag, prolonging the sedative effect. Frequent feeding by day and night, with occasional stimulation, he has found to produce quiet, and not only to prevent fatal exhaustion, but also to decrease the degree of dementia in cases that do not recover. The noisy condition of some foreign asylums, and formerly of English asylums, he attributes to under-feeding. Much exercise, either active or passive, and living much in the open air, conduces to quiet. The shower-bath is useful in certain cases; also blistering over the region of the ovaries in excitement due to ovarian irritation.

At the last annual meeting of the Association of Superintendents of American Asylums for the Insane, held in Philadelphia, the subject of chloral came in for a share of discussion. As physicians attached to lunatic asylums have probably more occasion to observe the effects of the drug than practitioners otherwise situated, the relation of their experience cannot fail to command attention. The remarks given below are taken from the report published in the MEDICAL RECORD, 1876, p. 436:

Dr. S. R. H. Smith, of Lunatic Asylum No. I, Fulton, Mo., introduced the subject of the use of chloral, which he considered a highly important one. He thought much injury was done by the injudicious use of this drug, and regarded it as a remedy which ought to be used with the greatest care and the results closely watched. He believed frequently the results of the chloral were mistaken for the regular progress of the disease, and that sometimes it had caused death. In chronic cases of insanity he regarded chloral as a very unsafe remedy; also in the cases of aged people.

Dr. Geo. C. Catlett, of Lunatic Asylum No. 2, at St. Joseph, Mo., said that he knew of three well authentic cases of death from the administration of ordinary doses of chloral as a sedative in cases of delirium from intemperance.

Dr. C. F. McDonald, of the State Lunatic Asylum for Insane Criminals, at Auburn, N. Y., states that on one occasion an attendant gave a patient two drachms of chloral by mistake. The patient suffered from acute mania, and soon after taking the dose fell into a heavy sleep, and afterward awoke quieter and calmer, and progressed to a complete recovery.

Dr. A. E. MacDonald, of the City Asylum for the Insane at Ward's Island, N. Y., considered chloral a valuable remedy, and had used it in his practice. He had never heard of a death said to be from chloral when the post-mortem examination did not reveal other causes for death.

Dr. Kirkbridge said that his sad experience with chloral had been that sometimes patients died unexpectedly to him, and he would not like his medical friends to administer it to him under any circumstances.

Dr. W. M. Compton, of the lunatic asylum, Jackson, Miss., said there were several noisy patients in his institution who had taken doses of twenty to thirty grains every evening for years, merely to quiet them and to put them to sleep, and he had never seen any bad effects.

It has been used with success by the following gentlemen: Drs. Clement A. Walker, Boston Lunatic Asylum; N. P. Bolles,[85] Dorchester, Mass.; Norton Folsom,[86] Boston, Mass.; R. W. Bruce Smith,[86] St. Thomas, Ontario; A. Ady, West Liberty, Iowa; Carlos F. McDonald,[88] James Donaldson,[87] London, England; E. Chenery,[86] Boston, Mass.; R. E. Sutton,[86] Rome, Ga.; James Perrigo,[86] Montreal, Canada; J. H. Etheridge,[86] Chicago, Ill.; H. C. Donaldson, Morrison, Ill.; C. H. Hughes,[86] St. Louis, Mo.; J. M. Pace,[86] Dallas, Texas; Wm. Judkins,[85] Cincinnati, Ohio; Q. C. Smith,[86] Austin, Texas; and H. Moe, of Chicago, Ill. All these are heard from by letter, with the exception of Dr. McDonald.

From the reports of institutions for the insane we make a few extracts in regard to the use of chloral:[89]

Dr. Earle, of Northampton, says: "For rapidity and certainty of effect in that direction (producing sleep) it appears to have no equal, unless it be opium. The sleep induced by it is more transient than that from opiates, but it has none of the disagreeable consequences that in some constitutions follow the use of them."

Dr. Brower, of the Eastern Virginia Asylum says: "We have made a thorough trial of the remedy, and are satisfied it is a valuable addition to our materia medica."

Dr. Lewis, of the Northern Ohio Asylum, says: "It is a valuable addition to our means of procuring refreshing sleep in those cases laboring under acute or chronic mania. As a hypnotic it is superior to opium, it having produced sleep when the latter has entirely failed."

Chloral has been used largely in the asylum since February, 1870. The whole amount used is ninety

pounds, which has been prescribed in three hundred and seventy cases, as follows:

Form.	M.	W.	Total.
Mania	69	119	188
Melancholia	30	59	89
Dementia	18	50	68
Paresis	12	1	13
Epilepsy	2	2	4
Employés	3	5	8
	134	236	370

The average length of time of administration has been, to the men, thirty-nine days; to the women, forty-three days. In a case of melancholia marked by the most distressing delusions and wakefulness, it was given in twenty-grain doses, for two hundred and fifty-seven nights, as a hypnotic, without losing its effect, and with the happy result of securing refreshing sleep. The patient recovered. In this case, as in others, the value of the remedy was tested by occasionally intermitting the dose. Sixty grains were administered during an attack of mania for one hundred and ninety-five nights in succession.

Dr. John Bowen, Riverside Hospital, this city, writes me as follows: "My experience in the use of hydrate of chloral is almost entirely limited to a two years' service in the New York Female Lunatic Asylum, of which institution I was formerly assistant superintendent. In the asylum we used hydrate of chloral to a very great extent, and I may add that my experience there caused my views concerning its use to undergo a very decided change. I sometimes use it at this hospital, in continued fevers, but generally in combination.

"My usual commencing dose is fifteen grains. The largest amount I ever gave at one dose was one drachm, and in twenty-four hours, two drachms.

"I have used it especially in delirium tremens, alcoholic, acute, puerperal and chronic mania, and to some extent in melancholia. I have almost invariably obtained good results from its use in all of the above enumerated diseases (when properly combined with food and stimulants), except melancholia. In chronic mania its effect was, of course, temporary.

"Case I.—Acute mania. Had not slept or taken food for six days. Gave one drachm of hydrate of chloral, two and a half ounces of whiskey, and one pint of warm milk, by means of stomach-tube. Put patient to bed, with artificial warmth to extremities, and watched her carefully. She went to sleep in less than an hour, slept for five hours, and awoke much refreshed. Chloral, in smaller doses, and milk were frequently repeated. Result eminently satisfactory.

"Case II.—Melancholia, attended with a good deal of excitement. Gave one drachm chloral and repeated it in two hours. Produced poisoning, with partial coma. Patient recovered from poisoning after the most careful and laborious attention."

In one case of mania, Dr. Frank L. Forsyth,[90] of Providence, R. I., found that chloral increased the symptoms.

INSOMNIA AND DELIRIUM OF FEVERS.

In the insomnia and delirium of the various fevers, chloral, in small doses, has proved itself an excellent remedy. It has been used for this purpose with success by Drs. A. A. Smith, of this city; H. H. Doane, Litchfield, Ohio; W. H. Travers, Providence, R. I.; Norton Folsom, Boston, Mass.; A. Ady, West Liberty, Iowa; C. C. Pike, Peabody, Mass.; J. W. Hickman,[91] Delta, Pa.; John Bowen, Riverside Hospital, New York city; G. W. Chamberlain, Hartford, Conn.; and J. A. Miller, Williamsburg, Ky.

Dr. Hickman says: "Exceptionally good results are obtained in inflammatory and febrile conditions when attended by delirium and wakefulness, with a high temperature. Recently, in a case of typho-malarial fever treated by the writer, chloral was found to control, in a most happy manner, the busy, exhausting delirium attendant thereon. It was administered by enema, and the sleep induced constituted the turning point in the case."

R. Fowler, of Aurora, Texas, lauds it as an efficient tranquilizer and sudorific in typho-malarial fever.

Roswell Park has employed it satisfactorily to calm nervous irritability and reduce temperature in fever.

Trelat[92] has found it of service in calming the delirium of erysipelas, as also has Dr. S. Teller.[93]

191 West Tenth Street, New York.

THE CLINICAL STUDY OF INEBRIETY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

The first impression from a careful study of many cases of inebriety is one of great astonishment that so little is known clinically of these cases, especially when they are found in every section of the country, and come under the observation of nearly every physician. No general record of cases or study of symptoms has been made, which indicates the origin, development, and character of inebriety; or the degenerations of the higher cerebral functions, manifest in impairment of the senses, and perversions of the emotions and will. Occasionally, for legal purposes, a lunacy specialist will attempt to classify the phenomena of inebriety, but always in the most vague and bewildering manner, simply because he has never made a clinical study of such cases. Not unfrequently such opinions are incorporated into psychological literature, and are accepted as authority, while clinically they are absolutely deficient of any information that exhibits the nature of this disorder. A general comparison of the theories and opinions of different writers, as to the nature and character of inebriety, indicates clearly that the time has come for a new study of the subject from a clinical stand-point. Here the first great fact that will be apparent is the correspondence of symptoms in every case of inebriety, no matter what the origin may have been. Between the two extremes of confirmed chronic inebriety, and the first toxic condition (or intoxication) from alcohol—a period exceedingly variable and uncertain—may be found groups of general symptoms, which indicate both psychological and pathological changes that march down with more or less uniformity. A closer study and grouping of the symptoms of a number of these cases gives unmistakable evidence of the presence of some laws and mutual dependencies, which extend through all the perplexing details, that can often be understood and sometimes predicted. Often the psychical symptoms exhibit a correspondence in their very per-

[93] N. Y. Med. Record, 1870, p. 574.

plexity that is amazing. Even the changes, variations, and long halts seen in the progress of many cases, appear to follow a certain law and order, which the limits of our present knowledge has only jointly discerned. In 1870 Dr. Parrish pointed out this fact, and showed conclusively that inebriety was not a disorder of accident, but that its origin, continuation, and decline, was governed by laws, modified by temperament, race, and climate, etc., which from clinical study would be well understood in the future.

My own experience, founded on the study of many cases, confirms this statement, and further indicates that future studies in this direction will reveal not only the general but special conditions from which inebriety takes its origin, but the laws which control its development, progress, and termination, and the methods of treatment founded on these facts will be eminently successful.

Inebriety is one of the insanities, less pronounced but more complex, lying on the border land, which shades down to the most emphatic mental disease on one side, and on the other, ranging up through all the various grades of nerve and brain disorder to health. Under the influence of alcohol, exhibiting marked symptoms of insanity, removed from this influence, the general appearance of health may be present; thus passing rapidly from one apparent condition to another, exhibiting a confusing chain of symptoms that cannot be understood without careful study. Through all this oscillation the line of disease is often obscure, partially masked, and cannot always be traced from step to step. Alcohol in most cases simply develops this condition of disease. I have no doubt that certain kinds of alcohol often determine the nature and character of the disorder, increasing or diminishing certain symptoms or complicating diseases, or intensifying the degeneration of this or that organ: but the general symptomatology and progress remain the same in all cases. No study of the pathological appearances, or morbid anatomy, will indicate the exact nature of the disease, because both the functional and organic condition of the brain varies constantly, from the slight excess of hyperæmia to the intense and widespread capillary engorgement, or to the exudation of inflammatory products into the tissues. Inebriety must be studied through its symptomatology; from trustworthy clinical records we shall be able to analyze all the disorders of the mental functions, of volition, intellect, and emotions, and the strange propensities which are displayed in a confused and ever-shifting mass, and recognize the diseased condition from which they spring. From the want of this study comes the vague and confused notions of inebriety. The following case is presented as indicating the character of the present study of inebriety in the profession generally:

Case I.—*Periodical inebriety—Inherited—Exposure—Periods of trembling—Delusions—Exhaustion—Great activity—Restoration—Relapse, etc.*—J. B——, aged forty years, an officer in a bank, was threatened with dismissal if he did not stop drinking. Consulted an eminent physician, who treated him with bromides, the continued current, and different preparations of phosphoric acid; urging him to gradually withdraw from spirits, and use beer and lighter drinks. He had drank brandy in excess for five years, most of the time with distinct intervals of sobriety, lasting from thirty to ninety days. For a year past these intervals had been shorter, and lately he had used brandy in small doses nearly every day at dinner. Receiving no benefit he employed another physician equally eminent, who advised a vacation and rest, with cinchona and coca, as steady remedies and as a substitute for brandy, light wines, and mineral waters.

The case finally came under my care, and I wrote to both physicians for a history of their diagnosis and treatment of this patient. The first one answered in a courteous letter of some length, describing the case as one of marked alcoholism, springing from bad company and fast life, and presenting no characteristics of anything worthy of the name of disease, except such symptoms as could be traced directly to alcohol. He had examined the patient in company with a lunacy specialist, and together they had failed to discover any mental defects; the real remedy seemed to him to simply break up his adverse surroundings, and impress on the patient's mind the personal responsibility and danger of continuing the use of spirits. He was agreed with his friend the lunacy specialist that medical treatment beyond the relief of temporary functional disturbances would be injurious, by creating in the patient's mind a hope of relief from sources outside of himself, and thus prevent exertion on his part. In his experience the use of the bromides and electrical current readily removed the effects of alcohol, and the lighter, purer drinks, such as wine, and sometimes beer, enabled the patient to break up the habit and become a thorough temperance man.

The second physician wrote that he had made a careful study of this case, and could not find any class of symptoms from which he could make out a disease. Possibly it was a mild case of alcoholism, for which the patient was most culpably responsible. But if he would give up his club, and join a church, he would fully recover. He had found congested liver, functional heart disorder, and dyspepsia, which were all local, and dependent on the alcohol used. He was undoubtedly suffering from a bad, vicious habit, which good surroundings and better company would do more to cure than all other means. Hence he advised that I should call in the aid of a clergyman and try to build up his moral nature. He thought cinchona was very useful, but was sure the sudden withdrawal of all spirits injurious, hence he urged light wines and mineral waters as a substitute. He closed his letter with a strong protest against calling drunkenness a disease, and thus setting up a refinement in science which was dangerous and misleading.

This summarizes the results, from the so-called studies of two excellent physicians, of this case. By one he was treated and under observation for over six months, the other was in charge for four months, affording ample opportunity to ascertain a full history of the case. My studies in this case were not only based on his own statements, but the testimony of his sister, the bank officials, and two of his intimate friends who had observed him in many different conditions. His father was an inventor, who lived in conditions of much poverty and case, and died of general paralysis at forty-two. His mother was a melancholy, dyspeptic woman, under medical care for a long period, and finally died of consumption at thirty-eight years of age. Her father (the grandfather) was a cattle-drover, and drank to excess at times all his life; both of his sons drank to excess and died early. Her mother died from cancer in middle life, and she was the only surviving one of the family. On the father's side of this patient, consumption seems to have been the special disease which appeared in all the members.

Nothing unusual was noted during childhood of this patient, except his extreme nervousness and excitability, which would come on suddenly and soon pass over. When seventeen years old he enlisted and went into active service at once in the Potomac army. Up to this time he had never been away from home, but had been occupied writing and drawing for his father, living a temperate, quiet life. From his own statement, he came back from a scouting raid one day, thoroughly prostrated, not having had any food for nearly twenty-four hours, and finding the water unfit to drink, used whiskey with marvellous relief, and from that time its use, when prostrated, seemed a necessity. He remained three years in the service, using alcohol to intoxication on many occasions. During the next twelve years he was engaged in life insurance and banking, and finally was promoted to cashier of a city bank. During the first five years after leaving the army he rarely drank to intoxication, and then only in secret, but always, when depressed and exhausted, the desire for spirits was intense, and had to be gratified. He claimed to be a temperanee man, and had a horror of being a druukard, disliked the taste of any form of spirits. As business cares and duties increased, he had attacks of nervous wakefulness at night, which nothing but brandy would relieve. Joining a club, he sought diversion and change, drinking only beer and light wines occasionally. The death of both parents and the breaking up of his home, threw him into a low, nervous fever for several days, during which he remained in bed, and drank large quantities of mineral water, giving as the only reason that they made him feel better. He resumed business for two days, then disappeared, and was found four days later in a hotel, intoxicated, where he had taken a room and drank steadily to exeess during this time. His recovery was rapid, and he seemed in better health and spirits for a long period. This was the beginning of the periodical attacks of inebriety. He lived with his sister, and was perfectly temperate and correct in all his habits of living for periods of three or four months, then he would disappear for a few days, giving some business excuse to account for his absence, and returning would seem more nervous and manifest an inordinate appetite for some days after. These attacks increased and the free intervals grew shorter; then he drank to excess in the club at night, and continued his business in the daytime, although under the influence of alcohol, more or less, for three or four days, then reformed, and was a rigid abstainer again for a long time.

These attacks were preceded by seasons of unusual activity at the bank, and great anxiety to provide against loss or danger from every source; such as re-examination of securities, and double caution in regard to doubtful clerks, and not unfrequently, when he returned home, he would be seized with muscular tremblings, and intimations of speedy death. In the presence of strangers or company he would control this, and appear to be in the highest spirits. Nights of wakefulness and wild dreams of injury would follow, and in the morning he would appear dejected and exhausted. Soon after he would be intoxicated. Generally he was noticed to drink first in the morning on the way to the bank, in a confused, hesitating manner; this would be repeated at intervals during the day. To the warnings of friends that he was going to be intoxicated again, he seemed entirely oblivious. Through business hours he was very sensitive and fault-finding. When his work was over at the bank, he either went home or to the club, and was profoundly intoxicated in a short time. Next morning he would be sober, go to the bank, drink moderately through the day, be intoxicated again at night at the club or at home. The third day would be a repetition of the others, only that he was less sensitive, seemingly more heavy and indifferent to the surroundings. On the morning of the fourth or fifth day he would rouse up, take an active cathartic, stop all stimulants, use beef-tea for two or three days, seem dejected, but very quiet and courteous to all he had found fault with before. Sometimes before and after these attacks his manner and habits seemed different. He was often secretive and suspicious, made extravagant promises, and complained that friends misrepresented his weakness; but always listened to temperance and vice, signed every pledge, and seemed anxious to recover. The result of the advice from the two physicians, was that he began to use brandy every day, and was intoxicated every three or four weeks. When he came under my care, he was filled with the delusion of strength to give up the use of brandy any time, but claimed he needed it for digestion, etc. He slept badly, complained of dreams of intoxication, and feared sudden death, or financial disgrace, and was confident a plot was forming to have him sent to prison. He suffered from periods of muscular agitation, and consciousness of inferiority and guilt. All these symptoms disappeared in a few weeks, and he entered heartily into every effort to help others. He seemed anxious to do all he could to build up his health for the future. At long intervals he suffered from dreams of intoxication, but sought relief at once from baths and medicines. He remained under treatment three months, and was obliged to return to the bank, or lose his position. He continued for nearly two years a temperate, hard-working man, then resigned his place to become president of a gold mining company in Nevada.

A few months after taking up a permanent residence in the neighborhood of the mine, he relapsed, and is now suffering from recurrent or periodical inebricty as before. I have purposely omitted all detailed studies of the symptoms, only presenting such general facts, which should have been noted in the observation of every physician. The origin of this case was very clear in the inherited nervous condition and general predisposition to this malady from his grandfather on his mother's side. The special exposure following the hardships of army life not only developed this latent neuroses, but gave it speeial form and character, which appeared in all his subsequent life.. The periodicity of the alcoholic excess pointed unmistakably to disease. A regular progression of symptoms was apparent in the early concealment of the attacks, and later in the boldness and indifference which he manifested as to his appearance, and the delusion that he was not noticed, or in any way different from others. The nervous exaltations and rapid changes of the emotions, also of the manner and disposition of the patient, both before and during the attaek, were strong evidence of disease; also the vague and confused manner in which the attack began, and the sudden termination from causes that were inadequate to bring on that result, such as a single dose of salts, or any earthartic that he fancied would answer, indicated a very significant mental disturbance. The increase of all the symptoms, up to the time of coming under my care, recovery and final relapse two years later, under conditions of great exposure, is a natural sequence, and confirms all previous indications. The danger

from failing to recognize the disease of inebriety in such cases, is in the neglect of prompt and efficient measures in the treatment. Had this case been recognized by the first physician, and put under the care of some one who could have regulated and controlled all his habits, and given him proper medical care for months or a year, the possibility of final restoration and cure would have been greatly increased. In my experience these cases can be treated with great success, in proper homes or surroundings conducted on exact hygienic conditions, and by suitable means adapted to each case, readily ascertained from clinical study. The natural tendency of every case is towards chronicity, complicating diseases, and death. Owing to the want of clinical study, or recognition by the profession, the case becomes chronic before medical aid is sought. Then follows a long period of empiric efforts to treat it as a vice, or sin, or some condition of the stomach or liver, or what is termed the weakened will. At length, when all other means have been exhausted, and the patient is in a confirmed chronic stage, it is suggested that a study of his case medically in some asylum might be of benefit. Three months in an asylum merely begins the process of restoration, when he comes out and soon relapses, and the inference from this, by his friends, encouraged by the physician, is, that asylums are humbugs, and the disease theory a fiction. This is repeated in every city in the country, and the poor inebriate, suffering from a malady practically unknown, sinks lower and lower to a dishonored grave. The number of inebriates in this country probably exceeds that of all the other cases of disease combined, and up to a recent period nearly all the literature of this subject has come from clergymen and reformed drunkards. To-day, from nearly every pulpit and lecture-hall in the land, clergymen and temperance lecturers are teaching the public what inebriety is, and how to treat it, and the profession acquiesce through silence. The teachings of patients who had recovered from typhoid fever or insanity, and the pulpit discussions of clergymen on these subjects, would be equally valuable as contributions to science. Inebriety must be studied clinically by the profession before its nature and treatment can be understood, and before any practical measures can be applied to prevent its growth and spread in every community.

A CASE OF

OBSCURE ABDOMINAL ANEURISM DIAGNOSED BY ASPIRATION.

By CHAS. A. HART, M.D.,

PLAINFIELD, N. J.

February 24, 1879, I was called by Dr. H. D. Burlingham to see John Slater, colored, aged forty-seven years, who had an obscure abdominal tumor. His principal occupation had been that of waiter. Had suffered from chills and primary syphilis. No history of general poisoning. Never had rheumatism. Had been rather intemperate. Has had pain in the lumbar region for five years, at times very severe, of a gnawing character. Was obliged to give up work a year ago on account of suffering. When standing, would incline the body toward the right side. The middle of the present month first noticed a small tumor in the right side below the ribs. Has been having daily chills without fever. Is considerably emaciated and unable to help himself. Pulse feeble, temperature normal. Not much pain except on motion. Urine charged with urates, but no albumen. The abdomen is distended by a tumor occupying the right hypochondrium and a portion of the left, extending nearly down to the crest of the ilium; the umbilicus is dragged about an inch to the right of the median line. Percussion dull from the sixth rib to the right anterior spine of the ilium. Surface of tumor generally smooth, but at one point nodular. General outline well defined and seems continuous with the liver. The growth has a very decided pulsation, *but no thrill or bruit*. The mass feels doughy but not fluctuant. Pulsation of right femoral artery less forcible than left.

From the above examination I was unable to decide the nature of the growth, but inclined to the opinion of aneurism of the abdominal aorta. Several physicians who had seen the case thought it either malignant disease of the liver or abscess. I next saw the case with Dr. Burlingham on March 5th. The tumor had increased greatly in size and seemed nodulated, with indistinct fluctuation, but still no bruit. The patient's condition being so deplorable, I determined to explore the tumor with a round-pointed aspirating needle, attached to a hypodermic syringe (reported in Medical Record, January 3, 1880), and settle the question of its nature. The needle upon puncturing the sac gave the sensation of having entered a cavity, and the *barrel of the syringe filled with arterial blood*. The tumor was undoubtedly aneurismal. No leakage took place from the point of puncture. The tumor continued to increase rapidly, and on March 19th the patient died suddenly, about six weeks from the time the growth was first discovered.

Post-mortem twenty-eight hours after death. Cadaveric rigidity slight. Abdominal cavity only examined. The tumor extended on the right side from above the free border of the ribs to the iliac fossa. The liver and intestines were crowded to the left side of the abdominal cavity. The ascending colon, vena cavæ, and the abdominal aorta, were found partly overlying the sac and closely adherent to it. The outer portion of the cyst was firmly adherent to the abdominal wall. A portion of the proper aneurismal sac, the size of the hand, had been absorbed, and its place supplied by the posterior abdominal wall. In the upper and posterior wall of the sac a large rent was found where rupture had taken place, giving exit to about two quarts of blood. A removal of the tumor showed its origin to be from the descending aorta, about two inches below the diaphragm. The opening in the vessel was three-fourths of an inch in size. A small portion of the sac lay over the spinal column. The last dorsal and first four lumbar vertebræ were found very much eroded, the second and third lumbar vertebræ were absorbed to the depth of three-fourths of an inch. The intervertebral substance had not suffered from pressure. The right kidney was found on the outer and anterior face of the sac, very much flattened, and was what had given the feeling of nodulation. The deposit of fibrin on the anterior side of the sac was quite thick, but thinned on the posterior. The aorta showed extensive ætheromatous deposits. I failed to discover the site of exploration. The obscurity of the disease, its rapid development after discovery, and large size, renders the case worthy of note. Without exploration I am at a loss to know how a diagnosis of its nature could have been arrived at with any degree of certainty.

Progress of Medical Science.

Obstruction of the Bowels Caused by Large Worms—Death.—In the *London Lancet* for Dec. 4, 1880, Dr. E. Downes has reported a case of intestinal obstruction caused by large worms. The patient complaining of constipation, purgatives were administered several times, but without avail. There was no indication of internal hernia. The abdomen was very much distended, and some coils of the intestines could be seen and felt pretty plainly through the abdominal walls. After a brief consultation it was agreed to perform Amussat's operation. Accordingly an incision four inches long was made about two inches above the crest of the ilium on the left side, and about parallel with it. On the morning of the third day, when evacuations occurred both from the artificial anus and the rectum, it was stated by the mother of the patient that an immense number of round worms, "about two pounds" in all, had passed by the wound. There seemed little doubt to the operator that the obstruction had been caused by the worms. The case terminated fatally a few days later.

A Recent Colles' Fracture Examined at Post-mortem.—The opportunity of examining a recent Colles' fracture at an autopsy was afforded Dr. Theodore A. McGraw, of Detroit, Mich. The patient, aged sixty years, had sustained a fall, and, in addition to a traumatic aneurism of the gluteal artery, fractured the radius. At the post-mortem examination the ulna was found in its place. No ligaments anywhere around the joints were broken or injured in the least, neither was there any extravasation of blood near the fracture. The lower end of the radius was broken into four fragments, which however, were, held together by the periosteum and ligaments. They were broken off the shaft just one half inch from the articular surface, and were inclined back with the characteristic deformity. It was with difficulty that they could be brought into proper apposition, and only by first making traction, and then bending towards the palmar surface. It was evident that they were held in their acquired position by bony impaction and by nothing else. It was difficult even when the bones were bare of flesh to get much crepitus, owing to the spongy consistency of the bone at that point.

Three of the lower fragments formed the dorsal rim of the articular cavity. The fracture had been undoubtedly produced by the sudden flexion of the hand and wrist upon the posterior edge of the radius. —*Detroit Lancet;* December, 1880.

On Chian Turpentine and its Uselessness in Cancer.—Dr. Henry Morris (*Lancet*, Dec. 4, 1880) denies the efficacy of this drug in the treatment of cancer, stating specifically that there is not a single symptom over which it seems to exercise any favorable influence. It cannot be relied upon to assuage pain, to diminish or alter the character of the discharges, to check hemorrhage, or promote the destruction of the growth by ulceration or sloughing. He has used it in twelve cases. In eight the female genital organs were involved, and in four the breast. Of the eight uterine cases five are dead, two are known to be extremely ill, and one, after a short trial of the turpentine, refused to continue taking it. This last is the only instance in which the turpentine was not taken for several weeks in succession. Of the four breast cases two are dead; a third is in the hospital, and the disease is very rapidly advancing, so that she will probably not live many weeks; while the fourth has the more chronic variety of scirrhus, which, after ulceration, heals in part and spreads in part. In the few cases where the patient at first thought she was benefited, the impression was due to that "clutching-at-straws" tendency that is so often observed in persons suffering from lingering and incurable diseases, and her being encouraged to think that she was taking a new and certain cure. Besides, it was not to be overlooked, in observing the effects of drugs on cancer, that some cases seem to halt in their progress, and stand still, for a longer or shorter time, while some even retrograde. A case of cancerous annular stricture of the rectum is cited to illustrate this point. Again, cicatrization of a cancerous ulcer, is seen every now and again, more especially in old people and in cancer of the breast; but the process is generally to be distinguished from the healthy cicatrization by the occurrence of fresh induration in or beyond the cicatrix. Again, one not infrequently sees cases where the whole of a large tumor of the breast has sloughed away by degrees, leaving a narrow sulcus or fissure, with perhaps a small flattened indurated ulcer at one part, partly scabbed over, and having shallow sulci radiating from it into the thickened parts around. In some of these cases it is hard to believe at first that an operation has not previously been performed. As a cure for cancer chian turpentine is utterly valueless.

Sir Henry Thompson's Operation for Cystitis and Enlarged Prostate.—Dr. Ashhurst has recently treated a case of cystitis with enlarged prostate and recto-vesical fistula, by Sir Henry Thompson's method of introducing a tube into the bladder through an opening above the pubes. The patient had for several months suffered from inflammation of the bladder associated with great enlargement of the prostate. There was no retention of urine, but, on the contrary, the bladder was much contracted, the patient micturating frequently and with intense pain, and the catheter not bringing away more than a fluid ounce of very offensive and dark-colored urine. The patient declared that there was an opening between the bowels and the bladder, but this was doubted by the doctor. Internal administration of ergot and chlorate of potassium having failed to give relief, Sir Henry Thompson's operation of establishing a direct communication with the bladder above the pubes was performed. The only point in which the operation differed was in the use of a metallic instead of a flexible tube. When the patient was visited in the ward, about an hour after the operation, it was found that fæcal matter was mixed with the urine which flowed through the vesical tube, thus showing that the patient's suspicion of an abnormal communication between the bladder and gut had been well founded. The operation was followed by no constitutional disturbance, and there has been measurable relief from pain. The enormous size of the prostate prevents any attempt at relieving the recto-vesical fistula by operative means.—*Medical Times*, Dec. 18, 1880.

Successful Removal of an Orbital Exostosis.—The following interesting case is reported by Dr. H. B. Sands, in the *Archives of Ophthalmology* for December, 1880: A young and healthy looking farmer had noticed a slight protrusion of the right eye for some three years, and had suffered subsequently

deep-seated orbital pain, headache, and vertigo. The protrusion gradually increasing, the right nasal passage had become obstructed. There was no impairment of vision. Finally he could hardly close the right lid. A firm smooth growth springing from the floor of the orbit seemed to be the cause of the difficulty. The sides of the nasal passage were closely approximated. No positive diagnosis was made, although the coincidence of exopthalmos with nasal obstruction led to the suspicion that the tumor was connected with the antrum. The patient consenting, the following operation was performed: A triangular flap, having its apex near the inner canthus, was reflected so as to expose the anterior wall of the antrum. This was cut away sufficiently to admit the finger, when it was ascertained that the cavity was empty. The eyeball being now protruded and pressed upward, the inferior edge of the orbit was gradually removed until the index finger could penetrate deeply enough to feel the morbid growth. This was found to be a hard, roundish body, a little larger than a large hazel nut, attached to the superior maxillary fissure. By the use of a chisel and an elevator it was removed, bringing with it a portion of the floor of the orbit. A horse hair drain was then introduced into the wound, which was closed with sutures. The patient did well after the operation, and left the hospital at the end of a fortnight. The protrusion of the eyeball had almost entirely disappeared, and vision remained unaffected. An examination of the tumor showed it to consist of a shell of compact bony tissue containing a large nucleus of cartilage.

Kassowitz on the Normal Development of Bone.—This process, which has attracted the attention of so many excellent observers recently, has been the subject of an extended treatise now going through the press. The views of the writer, as summarized by Maas, of Freiberg, are as follows: A question of surgical interest, namely, the growth of bone by apposition or expansion, is decided by recognizing the former as a normal process, while the latter is thought to be impossible, a view which is now very generally accepted. The development of bone from the periosteum is either direct, *i.e.*, without the intervention of cartilage, or indirect, *i.e.*, through this medium, which latter view is in opposition to that of most histologists. Cartilage, in the opinion of K., is produced where there is danger of the young bone being injured by external violence. In the growth of cartilage he believes that an interstitial expansion takes place and calcification is a sequence of the arrested expansive growth of the cartilage. Why this is not always the case is not explained. Giant-cells, which are associated with absorption of bone and are then designated osteoclasts (Kölliker), are not thought to be typical elements, but the transformed products of some fibrillar structure of greater or less size.—*Centralblatt f. Chirurgie*, November 20, 1880.

Tripolith as a Substitute for Plaster-of-Paris.—After a series of experiments Prof. von Langenbeck recommends this new material for surgical purposes. It was discovered by Schenk, and consists of lime, silicon, and the oxide of iron. Gray in color, and fine in quality, it is lighter and more durable than plaster-of-Paris, and, as it stands the weather well, was designed for stucco-work. It is applied in precisely the same cases as the plaster-of-Paris dressing, and in the same way. After enveloping the limb or body, as the case may be, in flannel, the gauze bandages that have been impregnated with the tripolith powder are immersed in water, then smeared with a thin paste of the tripolith and applied. The following advantages are claimed: It does not absorb moisture so readily as the plaster-of-Paris. Such dressings are lighter by about fourteen per cent., and more easily worn. After application they harden sooner (in three to five minutes), and when once hard and dry never absorb any moisture at all. It is possible, therefore, for patients to bathe while still wearing the tripolith dressing. It is also cheaper than the plaster-of-Paris.—*Berl. klin. Woch.*, 46, 1880.

Incubation and Diagnosis of Hydrophobia.—At a recent meeting of the French Academie de Médicine (*Le Courier médical*, Nov. 13, 1880), M. L. Colin reported a case of hydrophobia in a human subject which followed the bite of an enraged dog some five years previously. The case, however, seemed to lack inherent probability, judging from the symptoms which are now generally accepted as pathognomonic. In the discussion which followed, M. Bouley stated that he would base his diagnosis in such cases upon two points: first, the evidences at post-mortem, viz., apoplectiform foci along the floor of the fourth ventricle, the lymphatics and perivascular sheaths being filled with lencocytes, and, secondly, the inoculation of rabbits to determine whether the disease was true or spurious hydrophobia. On the former point, as remarked by M. Maurice Raynaud, the presence of these peculiar *miliary abscesses*, as they have been called, were valueless, since they have been seen by different observers in other morbid states. Inoculation of rabbits has also been tried in England to decide doubtful cases, but the results were often negative. It is now pretty generally recognized that laryngeal and pharyngeal spasm are the two most important elements in the diagnosis, while there is absolutely nothing distinctive in the pathological appearances; while inoculation, even with genuine rapid virus, only takes in a limited percentage of the cases. Certain individuals and animals have no susceptibility to the disease.

Abscess of the Liver treated by Subcutaneous Aspiration—Subsequent Discharge of a Biliary Calculus.—M. Guerin recently presented at the French Academie de Médicine a man upon whom he had operated for hepatic abscess. In January, 1873, he complained of pain over the liver and intermittent fever, which latter was relieved by quinine. Some months subsequently his pains returned, and a hepatic abscess was diagnosticated. A trocar was then introduced at the base of a large fold of skin, and the abscess cavity was cleared of its contents by aspiration. A rubber tube was passed through the wound, and frequent injections were made with carbolized water. Though the abscess seemed to close, not so the external wound. In the following year the patient returned to the country with the fistula still discharging. While absent he experienced a severe exacerbation of hepatic pain lasting forty-eight hours. He then expelled a biliary calculus, the size of a pea. Six months after there was a fresh attack, and a second calculus passed. Immediately thereafter the wound healed rapidly, and the patient entirely recovered his health.—*Le Courier méd.*, Nov. 20, 1880.

A New Method of Operation for Congenital Phimosis.—Dr. Demeaux, of Puy l'évêque, has devised a new and simple method for the operative

cure of congenital phimosis, with which he has already had pleasing results. He states that the operation is simple, short, devoid of all danger, unattended by loss of blood, and not followed by suppuration. It is described as follows: A strong silk ligature about one foot long, is well waxed and provided with two needles, one at its middle, the other at one extremity. A grooved director is now introduced under the prepuce and pushed as far as the end of the glans (sometimes not quite so far). The needle fixed at the end of the thread is then introduced along the director, made to pierce the skin at the termination of this instrument, and the thread is then drawn out. Now the second needle, with a double thread, is made to pierce the prepuce at its middle. The thread being cut, there are two loops, which are firmly tied, thus constricting the foreskin at two points. After five or six days, the ligatures have cut through the tissues and the prepuce is divided. In a fortnight or three weeks the cure is complete.—*Le Courier médical*, October 2, 1880.

The Functions of the Soft Palate and the Pharynx.—Dr. Falkson, of Königsberg (*Virchow's Archiv*, vol. lxxix., p. 477, 1880), had occasion to study this subject in connection with a patient whose naso-pharyngeal space had been opened to view by an operation in the orbital cavity. Speaking, swallowing, coughing, as well as deep inspirations, always produced conspicuous movements of the velum and upper portion of the pharynx. The soft palate participated, in a typical manner, in the process of articulation. A decided elevation took place with the pronunciation of every word or letter. This elevation of the palate was most marked with the letters *i* and *u*, less so with *e* and *o*, and least of all with *a*. Loud speech or mere whispering caused no appreciable difference in the extent of elevation. In pronouncing the consonants *m* and *n* no motion was visible. During speech the laryngo-pharyngeal space was never completely shut off from the naso-pharyngeal cavity. Falkson agrees with Voltolini in supposing the nasal twang of the voice to be independent of incomplete closure, since it occurred also when the velum was so placed as to make closure complete and perfect. The height of the voice does not at first materially influence the position of the velum; after a while, however, it invariably descends. Speech is more or less completely hindered if the movements of the palate are interfered with. During respiration there is no active participation of the velum. Snoring, on the other hand, is accompanied by a rise of the same, and a trembling vibration of the uvula and posterior palatine arches. Simultaneously the base of the tongue was seen to bulge upward. In deglutition the closure of the naso-pharyngeal cavity is very complete.—*Schmidt's Jahrb.*, vol. clxxxvii., September 27, 1880.

Gluteal Abscess following Child-Bed.—A. Davidson, M.B., M.R.C.S. Eng., Toronto, reports two cases of gluteal abscess which occurred in women shortly after confinement. The two cases here related are almost precisely similar, occurring, as they did, in young married women, in the same region of the body, during the winter months and following childbed. Case No. 1.—Patient had given birth to a child nine weeks previous to entering the hospital, but her lying-in was not attended with a good recovery. She complained of throbbing pain in the right buttock, which continued to increase in severity, resulting eventually in the formation of an abscess, which was opened and a quantity of pure pus discharged. The abscess-cavity measured about six inches in all its diameters. The after-treatment consisted in the introduction of a drainage-tube and the daily washing out of the cavity with a solution of carbolic acid (1–40). This mode of treatment was continued for some weeks; still the cavity did not seem to be decreasing in size. The walls of the cavity were then brought together and retained in this position by means of splints and a compress. This treatment was continued for two weeks, but without benefit. The patient became unruly and she was dismissed from the hospital before the wound healed. Case No. 2.—Patient had a good delivery; two weeks subsequently she observed a "dumb pain" in her right hip. When admitted to the hospital all the signs of a gluteal abscess were present. The abscess was opened under the carbolic spray, a drainage-tube was introduced and the wound dressed with antiseptic precautions. About nine ounces of thick, healthy pus was evacuated.—*Canada Lancet*, November 1, 1880.

Intestinal Croup and Diphtheria.—This is the title of a thesis for graduation, written by Schwarck, of Bonn. The author states that the disease occurs as primary diphtheritis, which is said to have an independent origin, and as secondary diphtheritis following previous affections of a different kind. There is no anatomical distinction between these two forms. Schwarck carefully studied a characteristic and typical specimen of diphtheritis of the colon, associated with evident dysenteric ulceration. The microscopical examination of the membranous deposits found in the colon revealed a structure altogether identical with that of similar membranes ordinarily observed in the fauces. The smaller patches showed a structure corresponding to that of the larger deposits. Both were said to owe their formation to the coagulation of a fibrinous substance, but neither the blood-globules nor the intestinal epithelial cells contributed to this formation. Lenticular products of exudation were discovered in the deeper layers of the mucous membrane, and these were thought to represent follicles degenerated by the croupous transformation, and surrounded by an area of infiltration. Such follicular exudations caused ulceration in consequence of sloughing. The arterioles in many places underwent a sort of hyaline metamorphosis, and becoming choked up also led to embolic ulceration. The local process in the intestines was for various reasons thought to be the result of constitutional disease. Finally, the author showed that a distinction between croup and diphtheria was inadmissible, inasmuch as the former might lead to ulceration just as well as the latter.—*Centralbl. f. klin. Med.*, No. 29, 1880; *Allg. med. Cent. Zeit.*, Oct. 13, 1880.

Occipital Neuralgia Cured by Nerve-Stretching.—Dr. Schüssler, of Bremen, treated a case of persistent neuralgia successfully by exposing the nerve along the course of which the pain was felt, and after carefully dissecting it out from its hyperæmic sheath, stretching it by digital force. The rather extensive wound healed by primary union, the operation having been antiseptically performed, although the spray was dispensed with. For a period of three days after the operation the patient complained of severe lancinating pains. On the fourth day no pain was felt, and since then she has never for a single moment complained of the least ache.—*Berl. klin. Woch.*, Sept. 27, 1880.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 15, 1881.

THE COMING MEETING OF THE STATE SOCIETY.

THE coming meeting of the Medical Society of the State of New York will, as usual, be one of the notable events of the year. The large membership which this association possesses, the representative character of its organization, and the intimate and peculiar relations which exists between it and the county societies of the state, invest its doings with an importance second to no similar society in the country, and give its decisions on medical legislation, and kindred matters, a corresponding weight. When it is stated that matters of some importance will be presented for action at this meeting the interest in the results will very naturally extend beyond the mere confines of this state. It is well known that through the action of this society a law has been created regulating the practice of medicine in this state. On several occasions we have referred to its provisions, to its practical workings, and its ultimate influences upon the suppression of quackery. This law has been in operation for a sufficiently long period to enable the different county societies to report upon its utility or to make any suggestions that may tend to improve its practical working. If any such reports are to be made, they will insure the attention of medical men everywhere, but more especially such as are watching the effects of the law with the view of securing the passage of a similar one in their respective states. No report will be more eagerly desired than one from the medical society of this county. But that such is not forthcoming may be in itself of the greatest interest, in view of the fact that as yet no means have been devised by the County Society for enforcing the law, except, perhaps, the extra assessment levied recently for such a purpose. But the legality of this measure is so seriously questioned that it has been referred to the State Society for action. There are very good grounds for supposing that the State Society cannot endorse this measure. If this be the case, no other county can follow the example of that of New York and provide an extra fund for the enforcement of the medical act. The question—which, in connection with the object for which the extra assessment was made, is of the greatest importance—may come up, as to whether it would or would not be desirable to alter the law limiting the membership fee of county societies to one dollar. There is no doubt that to the county societies belong the duties of enforcing the law, but how and by what means such duties are to be performed will not be so satisfactorily decided. This will be one of the points which will engage the attention of the society.

Another matter, of perhaps even greater importance, at least to the medical profession outside of the state, is the recommendation from the New York County Society, to the effect that a revision of the Code of Ethics be made. The Committee on Ethics of the County Society, at its recent annual meeting, made a very elaborate report, in which was set forth the necessities of such change from many points of view. These points are for the most part well taken. The committee state, with truth, that not only the state but the national code are more honored in their breach than observance.

With a desire to perform an unpleasant task, without giving unnecessary offence to any, the committee called the attention of the writers of several medical certificates to the by-law of the society forbidding the publication of said certificates. To its surprise the committee was answered by an advocacy of the principle of certificate-writing, and by a determination to continue the same, and this from leading members of the profession from whom we have a right to expect better things. In the report of the committee the subject of newspaper advertising in its various phases is discussed, particularly the fashionable form of personal interviews. The inevitable conclusion appears to be that there is no article of the code which cannot be conveniently evaded to suit the purposes of these advertisers. Between the duty of informing the public on medical matters and the wrong of advertising oneself as a practitioner of medicine there is a wide range of discretion allowed. Is it to be wondered at that any really public-spirited man should hesitate as to which course he should pursue?

Bearing upon these and other matters relating to an advocacy of revision of the code, the committee make the following statement, which we take occasion, in passing, fully to endorse: "In this connection, it may be pardonable for the committee to state that its experience during the past year has, in a forcible manner, demonstrated the inadequacy of the present codes of medical ethics to the existing demands of the profession. The code adopted by

the American Medical Association thirty odd years ago, has in many respects become obsolete; what were deemed offences then are no longer regarded in the same light. *Per contra*, the ingenuity of man has developed practices which were unknown when the codes, national and state, were established, and hence were unprovided for. The code of the American Medical Association contains a mass of sentimental advice, which, together with its moral platitudes and verbiage, would seem to suggest the necessity for its revision. Our own system of medical ethics, which the State Society adopted in 1823, and which has since been subjected to but few alterations, is perhaps even more obsolete than the code above alluded to. The profession is now in no sense guided by these codes; nor does it seem desirable to hold it together, either by the regulations that pertain to trades unions or by the moral platitudes of existing codes, but it rather requires for its wholesome government clear and business-like regulations, backed up by our ample statutory laws, leaving the matter of moral maxims and precepts, as well as personal manners, to the social conditions that surround the individual."

The presentation of this report to the State Society, and the indorsement by the County Society, will doubtless bring the question to an issue. There is but one way in which intelligent action can be taken upon it, and that is by recommending such alterations in the present codes as are consistent with the advances of civilization and with the corresponding demands of a liberal profession. The medical society can well afford to take the initiative in this matter, and prepare the way for the other states. Another point in this report which will doubtless require attention is, whether or no every member of the profession shall be compelled to join his county society, and also whether any member can resign at his option. The law on the latter is ambiguous enough to require further elucidation.

We do not undertake at this time to go over all the probable subjects which may be presented for decision at the next meeting of the State Society, but have referred to several which appear to have a leading significance, and which may serve as texts for our general remarks upon the importance of the coming meeting. There will no doubt be the usual supply of scientific material, and it is to be hoped that time and opportunity will be given for the discussions.

QUACKERY AND THE RELIGIOUS JOURNALS.

A PROMINENT religious journal, *The Evangelist*, has announced its position on the question of advertising quack nostrums. Its editors say that they do not claim to know anything about the genuine value of the panaceas they advertise. There may be, they say, something in them; one out of ten is very likely a "boon to suffering humanity." But they only present the claims of the drugs, with illustrative cuts and evangelical testimonials. Their readers can try them and thus learn what their therapeutical value really is.

The text which forms the basis of this argument is a flaming two-column advertisement of the "Only Certain, Effective, and Permanent Catarrh-cure." The remedy was discovered thirteen years ago, since which time it has presumably cured 60,000 cases. It is now sold only by a certain retired clergyman in an obscure western town, with whom all afflicted readers will please communicate.

The *Evangelist* states that it does not know whether the claims of this medical clergyman for his remedy are true or not. We find it very hard to believe this statement, or at least to believe that the *Evangelist* does not know that a large part of the very extravagant claims is not false. Could a man without medical knowledge have accidentally compounded an "only certain, effective, and permanent cure" for a chronic disease, thirteen years ago, without its yet being known to those most interested in obtaining remedies for this disease! Can any intelligent person read over the announcement in question and not believe it to contain many misstatements and gross exaggerations? But it is these which attract the attention, deplete the purses, and imperil the constitution of the readers.

The *Evangelist* argues that perhaps one-tenth of patent medicines may be useful, though the other nine-tenths are not. Therefore, for the sake of the tenth, a quasi-indorsement may be given of all. This is certainly Jesuitical reasoning.

Our estimable contemporary also thinks that it would be carrying principle to an extreme if the advertisement of a preparation of cod-liver, indorsed by some eminent and reputable medical men, were refused insertion. But this is a great misapprehension or evasion of the point. There is no objection to advertising any special drug or any mixtures whose formulæ are authoritatively known. But we protest against religious journals advertising, as specifics, secret preparations, whose properties may be injurious, and are always less effective than they are claimed to be.

Some religious journals would put the matter on a purely commercial basis, and end discussion by saying that "business is business." But it cannot be disposed of so easily. Religious journals pretend to have an object higher than that of simple financial success. They must guide themselves then by this high ethical standard which they would impose upon the world. And it is not in accordance with such a standard to circulate advertisements, nine-tenths of which, upon their own admission, are fraudulent.

We present an analogy: A city missionary goes about with a Bible in one hand and a package of handbills in the other. He proclaims the gospel

and distributes the handbills, remarking, parenthetically, "These tell of a very celebrated show; go and see it. I don't know anything about it myself, but it may benefit you; or you may get blown up during the performance—and this is more likely. It may do you neither harm nor good—I don't know anything about it; go and see for yourself; admission one dollar, one-fourth of which goes to myself."

The Apostle Paul said that some things should be avoided for appearance sake, even if not bad in themselves. This is an argument which we do not like to use in denouncing quack advertisements, but it may have force with some who have consciences too obtuse to appreciate the real condition of affairs. There is no doubt of the wide existence of a feeling against the practice of quack advertising in religious journals. It is shown by the cartoons in our weekly illustrated journals, and by the comments in the daily press. The advocates of the Christian religion should be above the reproaches and suspicion which the practice they now indulge in brings upon them. If they cannot see any harm in the practice, they must admit that others do. Is it better then to have the gold brought in by advertising a patent pill than to avoid all appearance of evil?

UNDERTAKING AS A HIGH ART.

We are glad to hear that the undertakers of this city are appreciating their high calling. A goodly number of the craft have formed themselves into a protective association, from which are excluded all persons who have not been regularly educated to the profession. It is high time that such should be done, and the undertakers who have thus boldly taken the stand against fraud and quackery should have the sympathies of members of the other liberal professions. The great causes for complaint among the mortuary artists are that mere sextons and livery-stable men commit fraud upon decedents and their friends by assuming the higher duties of the art when utterly incompetent for their performance, and also that they cheat the friends of the survivors of the melancholy satisfaction of paying the usual accessory fees. The consequence has been that men who know no more about trimming a coffin or dressing a corpse than they do about arranging the mourners or filling the carriages are monopolizing the profession and reducing it to the level of the merest trade. With a man who truly loves his profession and who has an eye to its æsthetical requirements, the situation is a painful one. The accessories of a funeral are everything to the undertaker. For upon these he must depend for the extra fees which give him a living. It is the proper management of these that give him a claim upon the community and entitle him to the rank which he now so justly claims. Naturally he will look to the medical profession for help in maintaining his rights. To such medical men as most frequently meet the undertaker he appears to be a man who deserves encouragement, and the feeling is doubtless reciprocated by him. At all events, he has been made to feel a sort of dependence upon the medical profession in many ways, and it is but just that it should not desert him in his hour of trouble. High art, æsthetical accessories, large fees, and the maintenance of professional tone are among the requirements of our advancing civilization. While the carpenter, the ice dealer, the trimmer, the florist, the livery man, and the grave-digger should have their due, the one who blends the doings of all into a harmonious whole must always claim his paramount professional rights. Unless he is enabled to do so, decent burials will probably be at an end; we shall have a return to the primitive and heathenish practices, and undertaking, as an art, will have perished from the face of the earth. That this should not be, was proven at the meeting by strong statements and by impartial arguments.

From the time that death was typified as a journey, the undertaker has been the toll collector. From the time that the coin for ferriage was placed in the mouth of the corpse until the present, when it is found in the pockets of the survivors, his profession has grown in influence and importance. We repeat, then, that his profession must be respected. Its members cannot too zealously guard against encroachments of the church-sweeper, the inroads of the hack-driver, or the meanness of the box-maker.

The organization has been effected none too soon. The next steps are the creation of a fee-table, a code of ethics, a training-school, and a register. Too much care, however, cannot be taken to exclude unworthy members. We would suggest to the active movers in the organization that many valuable suggestions as to the fitness and experience of candidates could be obtained from some of the members of the Pathological Society, or from such of the medical profession as are, by force of circumstances, compelled to attend the funerals of their patients.

We have said this much to commend the subject to the attention of such of our readers as might otherwise be apathetic concerning it. Not only should physicians do all they can to aid the undertakers in their struggle for existence, to help them in their efforts to elevate their profession, but should recommend to their patients only such of the craft as are qualified to perform the duties of their high office. If it were not that the undertaker's bill takes precedence in law of that of the physician, it would seem proper to recommend that the medical bills to survivors be low enough to allow for the necessary and extra charges for all first-class funerals.

THE NEW YORK SANITARY REFORM SOCIETY.

The New York Sanitary Reform Society has just completed its first year of work. It now announces

the results of its labors in a pamphlet which contains suggestions and statistics of much interest. The society in question has devoted itself chiefly to securing the carrying out of the Tenement House law, and it has worked very successfully in this direction. With the co-operation of the City Board of Health, this law has been more stringently enforced, builders being compelled to put in larger air-shafts and to curtail the percentage of lot occupied by the buildings. The prevention of the introduction of defective plumbing into tenement houses has also occupied the attention of the society. Largely by its earnest representation of the importance of this matter, the City Health Board resolved to enforce the law strictly in this respect, and oblige all plans of plumbing to be submitted first for approval. A third point dealt with by the society was in regard to the practicability of abating nuisances in a more summary manner than has heretofore been done. As is observed in the report, the *eventual* abatement of a nuisance is a very different thing from its *prompt* abatement.

For the future the society proposes to continue its work in reforming the condition of the tenement houses, and will try to secure a law extending the supervision of the Board of Health over the plumbing in all buildings hereafter erected in this city. Such questions as the proper construction of public schools, the cleaning of the streets, the sanitary education of the poor, the suppression of the Hunter's Point nuisances, and the licensing of milk venders, will engage the attention of the society in future. As its work has been judicious and productive already, we may expect much from its proposed labors.

Reviews and Notices of Books.

A Practical Treatise on Surgical Diagnosis. By Ambrose L. Ranney, A.M., M.D. Second edition. 8vo, pp. 471. New York: Wm. Wood & Co. 1880.

In this, the second edition, issued within a year after the first, the author has enlarged, amplified, and improved his work. The addition of some descriptive text beside the tabulated statement of signs and symptoms will make the book more intelligible and clearer; while not detracting from its value as a book for study, it will enhance its value as a book of reference. The introduction of a short sketch of the pathology and etiology of inflammation, in a condensed and readily understood form, will do much to throw light upon a subject which is apt to prove dark to the student, and a proper appreciation of which is too often wanting to the practitioner.

Of the work itself it is impossible to speak in too high terms of praise. No one who has never attempted the task can know the difficulty of arranging the principal characteristics of diseases which resemble each other in such a shape that, while their points of similarity are made known, the particulars in which they differ are made apparent. It is a work which requires not merely a thorough acquaintance with the subject, both in its literature and its practice, but also the mental faculty of grasping the prominent characteristics and arranging them so that word pictures shall be produced, similar yet different, vivid yet truthful. The man who has studied each individual disease and morbid condition may think that he understands it fully; still, it is only when he views it by comparison with another, when he arranges its salient points in tabulated form, that he fully grasps it and masters it. This is the work that Dr. Ranney has performed for us in his book; and the results of his labor are so nearly perfect that it is difficult to see how, in the present state of knowledge, they could be improved upon. The copious index at the end will tell the surgeon who is in doubt as to his diagnosis, where he may look, and when he turns to the page he may rest assured that he will find just what he needs.

Student's Pocket Series of Muscle Tablets. New York: Wright & Schondelmeier.

These tablets will be found useful by the student, as they are compact, and occupy so little space that they can easily be carried in the pocket, thus enabling the industrious to utilize their spare moments. They are five in number and give the names, origin, insertion, function, and innervation of the muscles, as arranged by Prof. Jos. D. Bryant.

How a Person Threatened or Afflicted with Bright's Disease Ought to Live. By Joseph F. Edwards, M.D. Philadelphia: Presley Blakiston. 1881. 12mo, pp. 87.

While devoid, as far as possible, of technical expressions, and written for general comprehension, this little book is a treatise on the hygienics of Bright's disease, from the perusal of which the professional man will be able to draw many valuable lessons. After describing the disease, and calling attention to its increasing prevalence, the author lays down the rules which should govern the afflicted. He regards it as hereditary. He advises exercise in the open air, avoidance of worry, residence in the country, a dry climate, the wearing of woollen underclothing, frequent bathing, keeping the feet warm, total abstinence from alcoholic drinks and tobacco, avoidance of excess of nitrogenized food, attention to the proper working of the bowels, and the securing of at least eight hours sleep daily. In short, the patient "should live reasonably and moderately."

Medical Heresies, Historically Considered. By Gonzalvo C. Smythe, A.M., M.D. Philadelphia: Presley Blakiston. 1880. 12mo, pp. 228.

The title of this book is unfortunately selected. The word heresy suggests unpleasant reminiscences of the inquisition and the rack, the *auto da fé* and the stake. Moreover, it fails to express the true character of the work. It contains an outline sketch of the principal sects which have flourished at different periods in history, as well as of their principal exponents. But the main portion, and by far its most valuable part, consists in a refutation of homœopathy, treating it not with ridicule but with serious argument. It shows the original character of this school by quotations from the writings of its founder, lays bare its transcendental character, its ignoring of pathology, its opposition to all scientific and physical knowledge. It exposes the absurdity of its fundamental doctrine of similars, and the impossibility of its numerous triturations and dilutions; and, finally, shows how, at the present time, many of those who call themselves homœopaths are teaching and prac-

tising something very much like what regular physicians inculcate. If a copy of this very readable, clear, and convincing book could be placed in the hands of every intelligent person who practices or supports homœopathy, they would see how egregiously they are being duped.

HORSES' TEETH: A Treatise on their Mode of Development, Physiological Relations, Anatomy, Microscopical Character, Pathology, and Dentistry, based on the Works of well-known Odontologists and Veterinary Surgeons; to which is added a Vocabulary of the Medical and Technical Words used. By WILLIAM H. CLARKE. New York: Published by the author. 8vo, pp. 262. 1880.

THIS work is largely a compilation from various authors. It is a very crude performance, showing neither good judgment or literary skill in putting the materials together. There is, however, a good deal of valuable matter collected in the book, and as it takes an unoccupied field, it will doubtless prove useful.

AN ELEMENTARY TREATISE ON THE FUNCTION OF VISION AND ITS ANOMALIES. By DR. GIRARD-TENLON. Translated from the second French edition by LLOYD OWEN, F.R.C.S.I. London: Baillière, Tindall & Cox. 1880.

THE object of this little work is to place the principles of the more abstruse portion of modern scientific ophthalmology within the reach of the general practitioner. The author has, on the whole, succeeded in this object remarkably well. The only criticism which can be made is, that the condensation is in parts too great, and some of the technicalities may be found not to be sufficiently explained. This is, however, more pardonable than the opposite extreme, now so fashionable, of popularizing specialities, so that they will appeal to the laity almost as much as to the general practitioner. The book is still thoroughly scientific in its treatment of subjects. We can heartily commend it as being, in the field which it covers, a very useful manual.

IS CONSUMPTION CONTAGIOUS; and can it be transmitted by Means of Food. By HERBERT C. CLAPP, A.M., M.D. Boston and Providence: Otis Clapp & Son. 1881.

THE question of the contagiousness of consumption is one of much more pathological than of practical interest. Hundreds of thousands of people die annually from phthisis. If out of this vast number a few cases of apparent contagion are found, the immense remainder should also be remembered. We have little sympathy with the alarmists who would popularize the idea that phthisis is contagious. Dr. Clapp can hardly be classed with "alarmists," but he evidently wants to believe in contagiousness, and his bias has impressed itself on his study. His book is chiefly a collection and study of the evidence favoring the theory of contagiousness. As such, it has considerable value, and will fully repay perusal. The latter part of the book is devoted to the question whether consumption can be transmitted by means of food. This we regard as a much more serious question, and one deserving the earnest attention of physicians. It is not a settled question as yet, however, and Dr. Clapp has added nothing new to its solution.

THE INTERNATIONAL SANITARY CONFERENCE met on January 4th, but, owing to the non-arrival of several delegates, adjourned until the 12th inst.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 27, 1880.

DR. A. E. M. PURDY, PRESIDENT, IN THE CHAIR.

CERTIFICATES of membership were presented to DRS. Wm. C. Gilliam and Edward A. Judson.

ANÆMIA IN INFANCY AND EARLY CHILDHOOD.

DR. A. JACOBI read an elaborate paper upon the above subject, in which he directed special attention to the fact that, although the condition was so frequent and so dangerous, and one which deserved to be treated of by the best men among practitioners and writers, yet there was no text-book in which a comprehensive study of the subject could be found. In the large majority of instances the condition was secondary in character, although the author of the paper maintained that there were cases of idiopathic anæmia, that is, idiopathic in the same sense in which the term idiopathic pneumonia or idiopathic peritonitis is used. Every disease occurring in infancy and early childhood might give rise to anæmia. For example, all the various hemorrhages resulted in anæmia in many instances, because infants resisted them much less than do adults. Premature children, also those born with congenital diseases, were especially liable to become the subjects of anæmia. Diseases developed in later life might result in that condition. For example, endocarditis, protracted diarrhœa, constipation, malaria, prolonged albuminuria, pernicious anæmia, of which two cases occurring in children had been recorded, leucæmia, leucocythæmia, sleeplessness from any cause, mercurial cachexia, hereditary or congenital syphilis, rachitis, fatty liver, enlargement of lymphatic glands, the complex phenomena grouped under the head scrofula, diseases of the bones, of various kinds, and diseases of the lungs and the pleura.

In anæmia both skin and mucous membrane were pale, of a yellowish hue, thin and flabby. Those organs or tissues which were least used, emaciated first; thus, in very young children fat and muscle were first affected. But there were cases in which fat was persistently retained, and in which it even increased in quantity. For, when the red blood-globules were destroyed there was scarcity of oxygen for the completion of the combustion of albuminous substances; and fat, the physiological result of such incomplete combustion, was deposited in large masses. Particularly was that the case when anæmia was either complicated with or resulting from general rachitis, and when at the same time the glands of the chest were suffering from the results of rachitic processes.

In consequence of anæmia all the organs were, functionally, considerably affected, and with the debility there was a corresponding irritability. The nervous system was less affected than any other, because of the rapid growth and development which occurred during that period of life. Not unfrequently were anæmic and emaciated babies in the best of spirits, because their brains were comparatively in good condition. Every baby with considerable depression of the fontanelles must be considered

as being in danger from the very degree of inanition present.

Murmurs in the jugular veins were not very frequent in infancy and early childhood. Murmurs in the carotids and over the large fontanelle were not at all rare. It was not true that murmurs audible over the brain belonged to rachitis alone; for they might be found in every condition in which blood pressure in the large arteries in the cranial cavity was lessened. The heart itself seldom exhibited functional murmurs. They were so rarely found in the functional disturbance of infancy and childhood that whenever they were heard it was safer to attribute them to organic disease than to merely functional conditions.

Although the brain itself was not so liable to suffer from emaciation, depending upon anæmia, as were other organs, still there were a number of cases in which headaches, attacks of syncope, sleepiness, or, on the contrary, sleeplessness and hysterical attacks, were the result of anæmia only, and disappeared when that condition was relieved. Not a few of the babies and children who cried the greater part of the night had no other ailment than general anæmia, and were frequently relieved by a meal, or some stimulant either before they were put to bed, or given during the interruption of their sleep. The pulse of such children was sometimes very much accelerated, while at other times it was slow and even irregular. Perhaps the pulse was among the symptoms which were the least reliable at that age. In babies it was counted best during sleep, and better over the fontanelle than upon the radial artery.

Anæmic children rarely had a good appetite except in the beginning. The circulation was deficient, and consequently the normal secretions were either defective or deficient. Therefore both appetite and digestion were impaired, and sometimes destroyed.

There was one consequence of the anæmic condition which was of the utmost importance, and which carried with it the indication for its removal in the shortest possible time. It was that whenever any disease set in it was not only more liable to terminate fatally in consequence of the impaired powers of resistance, but when there was the slightest tendency to effusion or exudation those processes would become more extensive, and in less time than in the normal organism. Pneumonia or peritonitis or pleurisy occurring in an anæmic child was a great deal more dangerous than when either of those or any other disease attacked a child in a good, general condition. The author of the paper then spoke of predisposition to and special causes of anæmia. Improper feeding and food were very frequent causes. For the author's views upon that part of the subject the reader was referred to his article on "Infant Hygiene," in the first volume of Buck's "Hygiene." Special reference was made to the deleterious effects of nursing children after they were nine or ten months old. Lactation and pregnancy also were incompatible.

HYGIENE, INFANT FEEDING, AND REMEDIAL TREATMENT OF ANÆMIA.

Barley-water and cow's milk would make better muscle than poor, mother's milk. Avoid solid food, in the main, for infants. Avoid cow's milk, either undiluted or diluted with water only. Avoid condensed milk diluted with water only. Use no milk without the addition of some gelatinous or farinaceous decoction, such as barley-water, etc. In anæmia add beef soup. Solid food might be given at the end of the first year, and such articles might be slowly added to the diet list as physiology and experience permitted. Prohibit, as bad habits, irregular and fast eating. Enforce out-door exercise. Avoid crowded school-rooms and excessive private lessons. There were laws to protect children against cruelty in various directions, but none to protect them from equally injurious influences in various other directions. Too many books were bought for Christmas and too few skates.

Among the remedial agents iron had long been resorted to in the treatment of anæmia and chlorosis. Whether or not it was the iron which produced the beneficial effect had not been answered to the satisfaction of all; for, a great many of that class of patients recovered in consequence of change of diet, with rest and an improved general nutrition, and without the use of any iron whatever. Besides, there were a number of cases in which the administration of iron had been absolutely unavailing. Moreover, there was plenty of iron in almost every article of food. Certainly the doses usually given were large when compared with the iron contained in the food, and with the amount of iron (three grammes and no more) present in the whole quantity of blood circulating in the human body. But it had not been found whether the iron did not act in some way other than by increasing the amount of the metal contained in the hemoglobin. There was no doubt, according to Dietl and Heidler, that it was absorbed in the stomach, and also, very probably, in the upper part of the small intestine. It reappeared in the bile, the pancreatic juice, and the intestinal secretions, not only after it had been taken into the stomach, but also after it had been injected into the veins. The preparations which, in his opinion, were the most beneficial in anæmia of children were the lactate, the tincture of the pomate, the pyrophosphate, the subcarbonate, and the tincture of the chloride. The syrup of the iodide was indicated where, in addition, an absorbent was indicated: as for example in slow convalescence after inflammations resulting in exudation, and specially in disease of the glands and lungs. The subcarbonate combined with three times by weight of subcarbonate of bismuth, and three or four times by weight of bicarbonate of soda, was especially beneficial when gastric catarrh interfered with general improvement during slow convalescence or progressive anæmia. The tincture of the chloride must be regarded as a vascular irritant, and, whenever the action of the heart was lowered and blood pressure was lacking, it was *the* preparation which would be found to be most beneficial.

It had seemed to him that the pyrophosphate was the preferable preparation in cases of anæmia with gastric catarrh, and catarrh or digestive incompetency of the upper portion of the small intestine. The compound hypophosphites and the phosphates he had used with good results, notwithstanding their elimination was nearly as rapid as their ingestion.

In cases of chronic anæmia he had also used arsenic with benefit in minute doses daily after meals, and well diluted with water, especially in a peculiar torpid condition of the stomach which would not digest and assimilate in consequence of absence of both nerve power and gastric juice. It might be given with iron, with or without stomachics. Strychnia, also, in his hands, had proved very useful as an adjuvant to either iron or arsenic, and to a child two years old it might be given with safety in doses of one-fortieth of a grain daily, and continued for

a long time. He had also used phosphorus in substance, in minute doses, with good results.

Cod-liver oil in many cases was beneficial, but frequently its contraindications were overlooked. Most children did not bear it well in the summer time. Some did not bear it at all. At all events, it should not be forgotten that, whenever digestion was impaired and gastric catarrh was present, preliminary treatment was required before the administration of either cod-liver oil or iron.

SPLINT FOR COLLES' FRACTURE AND A NEW FRACTURE-BOX.

Dr. W. P. Bolles, of Boston, on invitation, exhibited a modification of Gordon's and Bond's splints for the treatment of Colles' fracture, and also a fracture-box made up of a series of segments strung upon steel rods with thumb-screws, by which segments could be loosened and tightened as the surgeon might desire.

The President announced the death of Dr. Edouard Seguin and Dr. Nelson Clements, Jr.

THE INDEX MEDICUS.

Dr. Jacobi directed the attention of the society to the value of the subject catalogue of the National Medical Library, and also spoke of the Index Medicus, urging members to subscribe for that publication, at least, until the existence of the work was fairly established. Subscriptions to cover $1,200 were needed.

ASSESSMENTS IN COUNTY MEDICAL SOCIETIES.

Dr Ellsworth Eliot offered the following resolution, which was adopted:

Resolved.—That our delegates to the State Medical Society be instructed to obtain from the State Medical Society an opinion whether a county society can legally lay an annual assessment or tax of any amount, or whether the laws of the state limit the amount of the annual tax or assessment which a county society can impose.

On motion by Dr. F. V. White, the society gave a vote of thanks to Dr. Jacobi for his interesting and most valuable paper, and also to Dr. Bolles for exhibiting his ingenious surgical apparatus.

The society then adjourned to meet on Monday evening, January 10, 1881, when Dr. C. L. Dana will read his prize essay "On the Benignity of Syphilis."

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 23, 1880.

Dr. H. B. Sands, President, in the Chair.

Dr. C. T. Poore reported a fatal case of

LIGATION OF THE EXTERNAL ILIAC ARTERY.

Dr. Briddon thought that to him the credit belonged of opening the peritoneum, as it was through his suggestion that the mistake was made. He believed, however, that opening the peritoneum had nothing to do with the fatal result, as the autopsy showed that it had united by first intention.

Dr. Poore's case was the third in which he had seen serious hemorrhage follow a sloughing phagedenic chancroid. In one case the attending physician stated that the stream of blood was so large that he did not see how it could come from any other artery than the femoral, but when Dr. Bridden had arrived the hemorrhage had ceased, and it was not deemed prudent to disturb the wound in order to find out from which vessel the blood came. The hemorrhage did not recur. In the second case the hemorrhage was of a similar character, not so profuse as in the first one, and there was a large sloughing ulcer upon the inner and upper aspect of the femoral region. The hemorrhage had ceased when he arrived, and it did not recur.

He had seen several cases in which very profuse hemorrhage had occurred from the dorsal artery of the penis, as a complication of sloughing chancroid, and immediately after the cessation of the bleeding the healing process went on very rapidly.

Dr. T. M. Markoe referred to a practical anatomical point in connection with the ligation of the external iliac artery, namely—the fact that there is a much looser connection between the peritoneum and the fascia transversalis in the immediate neighborhood of Poupart's ligament than there is above; and that fact had been utilized in selecting that precise location in which to perform the operation, because the surgeon could, with a very great degree of certainty, there distinguish the two tissues. That certainly was still further increased by the quantity of fat which was found between the peritoneum and the fascia transversalis at that point. In proportion as the surgeon went above Poupart's ligament, the ability to distinguish between the two structures diminished.

Dr. Briddon remarked that the fat referred to by Dr. Markoe was rarely absent, even in the most emaciated subjects.

Dr. L. A. Stimson asked for the opinion of the Society concerning the advisability of seeking for the ends of the bleeding vessel in the wound rather than ligating the vessel in its continuity above the seat of hemorrhage. Not infrequently, in cases of severe hemorrhage, it is not demonstrated that the main artery is involved. In a case recorded by Liston, the external iliac was tied for hemorrhage, supposed to come from the femoral artery. The patient died of gangrene, and at autopsy it was found that the hemorrhage was from a branch, and not from the main trunk of the femoral.

Again, even though the hemorrhage be controlled by the ligature above, was that a guaranty that bleeding would not occur from the distal end of the vessel? The presence of ulceration over the vessel was not proof that it could not bear the ligation safely. In other words, would not the indication be, if unable to control the hemorrhage by pressure, to seek for and secure the vessel with two ligatures, one just above and the other just below the opening in its coats.

Dr. Briddon said that he should be very loth to apply a ligature around a vessel in a wound that was continuous with the sloughing surface of the original bubo; for it was very probable that the sanious discharge from the sloughing surface would invade the deeper incision and produce disastrous results.

Dr. A. C. Post recalled a case which came under his observation when House Surgeon in the New York Hospital. Dr. Valentine Mott was the attending surgeon, and he performed amputation of the leg. Copious secondary hemorrhage took place from the stump. Dr. Mott came and tied the femoral artery. In the course of a few days hemorrhage occurred from the femoral where it was ligated, and Dr. Mott then tied the external iliac artery. A few days later hemorrhage occurred from the point where it first took place from the femoral, and a consultation was held with reference to ligation of the primitive iliac; but while it was being held the

bleeding was so copious that the bed was soaked through, and a puddle of blood was formed upon the floor, and the patient was so reduced by the loss of blood that the proposed operation was abandoned as hopeless. But that state of extreme prostration arrested the hemorrhage, there was no further recurrence, the patient rallied rapidly, and within two or three weeks he eloped from the hospital upon crutches. The case was interesting as illustrating that hemorrhage from a very large artery sometimes ceases without operative interference.

Dr. Briddon thought that surgeons were apt to interfere too soon in cases of secondary hemorrhage; yet, unless they had trained assistants, they did not feel safe in leaving the patient, in most instances, without having placed a ligature around the vessel.

Dr. Chas. McBurney asked: "Is it not sometimes erroneous in operations in this region (that embraced in Dr. Poore's communication), in cases in which the fascia transversalis is made a landmark, to look for a perfectly distinct tissue?" In attempting to demonstrate this fascia upon the dead body, he had, in a number of instances, failed, although full opportunity was afforded to make a large flap, and the fascia was found to consist of nothing more than a loose layer of connective tissue. In such cases, after cutting through the muscles, if one was to depend upon finding a dense membrane, and was always willing to cut through the first really *dense* membrane found next to the muscles, one would cut the peritoneum itself. He thought that the usual rule given was incorrect; certainly it did not hold good upon all dead subjects.

Dr. Briddon thought it was the safer method to divide the muscles, and not attempt to divide the fascia transversalis. As soon as the surgeon could lift up the peritoneum it was best to cut.

Dr. Stimson referred to an advice given by Tillaux in a recent book, namely, not to attempt to divide the fascia transversalis, but to tear it off as soon as the muscles are divided. Dr. Stimson doubted its practicability in all cases.

The President agreed with Dr. Briddon with reference to the ready separation of the peritoneum from its attachments, as a test of its having been reached, but differed with him as to the necessity for cutting through the fascia transversalis. It seemed to him that a great deal of embarrassment was caused by failure to divide the fascia transversalis when that membrane was well developed. If the surgeon cut upon the fascia, and did not cut through it, he would find it a difficult matter to strip it from the iliac fossa; and if force was employed, and the tissues were stripped up, not only would the peritoneum be raised, but the layer of fascia beneath the artery, and he would fail in exposing the vessel with that nicety which was desirable before attempting to surround it with a ligature. Dr. Sands was quite sure that unless the fascia transversalis was divided, the subsequent steps of the operation were likely to be difficult.

Dr. Markoe questioned the soundness of the general view expressed by Dr. Briddon, that surgeons were apt to interfere too early in cases of secondary hemorrhage. His impression was that more lives were lost by waiting too long than by interfering too soon. He thought that the surgeon was apt to be misled by the fact that the hemorrhage had ceased after it had recurred several times, and was thereby deterred from operating, whereas if he had operated at once after the first recurrence more favorable results would have been obtained. Dr. Markoe was perfectly satisfied that it was an error to postpone interference in cases of recurring hemorrhage in necrosis, but then, however, there was a specific reason for a prompt operation; but, in general, he believed that an error was made more frequently by postponing than by operating too early.

Dr. Briddon said that his remarks were to be applied only to those cases in which the secondary hemorrhage had ceased; perhaps temporarily, perhaps permanently.

Dr. Poore asked if such cessation occurred when the blood came from a large artery, and Dr. Briddon replied that it did.

Dr. Markoe said that it was by far the most common fact, in cases of secondary hemorrhage from a large vessel, that the hemorrhage ceased as soon as the patient became faint, and he believed also that it was that very fact which was apt to mislead surgeons.

He further asked Dr. Briddon how many times hemorrhage had occurred in the cases to which he referred, and Dr. B. replied that only a single hemorrhage occurred.

Dr. Markoe then stated that a single hemorrhage would not justify an operation for securing the vessel; but, when hemorrhage recurred, that fact justified an *immediate* operation; for in nine out of ten cases the blood came from a large vessel.

Dr. Briddon remarked that in this second case the hemorrhage was profuse, but it came from the superficial circumflex instead of the femoral. He thought that in the majority of cases in which the irritating cause was a sloughing chancroid, the sloughing process rarely extended beyond the deep fascia.

Dr. McBurney asked Dr. Briddon whether he would interfere at once or would wait in a case in which hemorrhage had recurred three or four times and the evidence pointed toward an opening in the femoral artery.

Dr. Briddon thought that if the hemorrhage had occurred more than once or twice it would not be safe to leave the patient. In his previous remarks he referred to operating directly after the first occurrence of secondary hemorrhage. But he considered the occurrence of secondary hemorrhage a number of times as an indication of a tendency to further recurrence; therefore the propriety of interference.

The President regarded the question raised by Dr. Markoe, as to the necessity of early interference, as an interesting one, and agreed with him as to the propriety of operating without delay, if pressure failed to control the hemorrhage. He had, however, seen a number of cases of hemorrhage from arteries of large size tied in continuity, which had been checked by pressure made either with the fingers or with some form of mechanical contrivance. When he was House Surgeon in Bellevue Hospital Dr. Wood tied the external iliac artery for the cure of a femoral aneurism. One or two days after the separation of the ligature, the patient had a copious bleeding, and it was thought that he would die. He recovered, however, under treatment by digital compression exerted for the greater part of one day and afterward followed by the pressure of a shot-bag.

Dr. Sands also referred to a case in which Dr. Willard Parker tied the carotid artery for an erectile tumor of the scalp, the patient being a child and the disease congenital. In that case the patient, shortly after the separation of the ligature, and while running about the yard, was seized with hemorrhage, which was permanently checked by digital compression.

He also referred to a case in which he tied the carotid and the subclavian arteries for the supposed aneurism of the innominate artery. That patient had two attacks of secondary hemorrhage from the carotid, which was checked by a graduated compress, and did not seem to retard recovery.

He once assisted Dr. Parker in tying the femoral artery for popliteal aneurism, and that patient had a tolerably profuse secondary hemorrhage, which was arrested by the application of a compress, and a bandage being applied to the limb from the toes up to the groin.

He agreed with Dr. Markoe that no time should be lost after hemorrhage recurs, and he supposed the only reason why the rule was not always followed of cutting down upon the artery and tying it, as in a case of primary hemorrhage, was the softness and lack of resistance of the coats of the bleeding vessel. But he thought it should be the rule, with few exceptions, to open the wound at the point of lesion, and tie whatever artery might be found open, if it would bear the ligature. In any case, there were great objections to tying the artery in its continuity, because the operation was not sure to check the hemorrhage, although it seems to have done so in Dr. Poore's case. Again, in the lower extremity it was almost certain to cause gangrene, because it rendered necessary the maintenance of the circulation through two sets of collaterals instead of one. Some surgical writers have stated that when a ligature is applied to the superficial femoral, and one subsequently to the external iliac, gangrene is inevitable. This is not so, however, as he had had occasion to observe, in a case in which Dr. Stephen Smith tied both these arteries, in Bellevue Hospital, and gangrene did not follow the operation. But the vitality of the limb was greatly reduced, and every winter, for several years, the lad came into the hospital to be treated for superficial gangrene of small patches of integument that could not resist the effect of extreme cold.

Dr. Markoe thought that the cases in which secondary hemorrhage occurred after the vessel had been ligated in its continuity, differed in character from those in which the hemorrhage took place from ulceration or sloughing. In the artery tied in continuity the ligature is supposed to be passed through healthy tissue, and it is hoped that the plug has already formed, so that the bleeding which occurs finds its way alongside of the plug, and all that is necessary is to support by moderate pressure the plug, which already partially restrains the flow of blood, and the patient will often recover. He thought there was an essential difference between the precept founded upon those cases and that founded upon cases in which the opening made in the artery was the result of ulceration or sloughing.

The President said that he recognized that difference very decidedly. He would say that, in the case of an artery opened by ulceration, the practice should be, if possible, the same as that followed when the artery was divided with the knife, namely, to tie above and below the point of lesion in the artery.

Dr. Briddon asked if the President would recommend that operation when the ulceration was of the character of a sloughing phagadena, and when the artery would be left as a part of the ulcerated surface?

The President replied that while every case must be judged of by itself, it was expedient to tie the artery at the lowest point where it would hold the ligature, so as to diminish the chances of secondary hemorrhage and gangrene.

Dr. Markoe thought that the rule enunciated by the President would hold good, except in cases in which the tissues were disorganized and presented an obstacle to tying the artery *in situ*. The law was to tie *in situ*, if possible, and the exception should be made only where the condition of the tissues in the wound was such as to forbid its application.

Dr. Briddon believed that the incision would undergo the same destructive process as existed in the original ulceration.

Dr. Post suggested that the same law would apply to wounds that remained open for a week or more and were filled with granulations. The first capital operation he ever performed was in a case of that kind. He was called to see a man who had cut the lower part of one of his legs with an axe. The physician who was called did not tie the bleeding vessel, the anterior tibial artery, but relied upon pressure, and when Dr. Post saw the patient the wound had granulated, and it seemed to him to be impracticable to find the artery in the wound, and he ligated the femoral. But the operation was ineffectual, hemorrhage recurred a number of days afterward, and was finally controlled with the actual cautery.

NEW YORK ACADEMY OF MEDICINE.

OBSTETRIC SECTION.

Stated Meeting, December 23, 1880.

Dr. Salvatore Caro, Chairman.

ABSENCE OF THE LABIA, CLITORIS, UTERUS, AND OVARIES, IN A PERSON FEMININE IN APPEARANCE.

The Chairman narrated a case as follows: An Italian woman, aged twenty-nine years, had been married nine years, but was sterile and had never menstruated. For many years she had suffered from periodic attacks of great distress in the precordial region, resembling angina pectoris, and for relief she had been always bled and physicked. Between two and three years ago she came to the United States, and the distressing attacks have continued without special modification, although she has been blistered, bled, cupped, and purged. In September last she came under Dr. Caro's care, and he found her with a rapid pulse, 112, face pale, difficult respiration, skin of a yellowish, sallow hue, and she could only with difficulty be aroused so that she would speak. The cardiac attacks had appeared regularly every month for several years. Nitrite of amyl relieved her entirely of all precordial distress.

On making an examination to ascertain, if possible, the cause of the sterility and the absence of menstruation, Dr. Caro found a conical vagina about two and a half inches deep, and very narrow. He was unable to find any uterus, except a rudimentary nodule about the size of a small hemp seed. He was unable to detect any ovaries. There were no labia. There were only a few hairs on the mons veneris. There was no clitoris. The patient had never had any sexual desire whatever. The breasts were well developed, looking like virgin mamma, but there was no areola, and only a rudimentary nipple, which was very small and did not differ in appearance or feel from the skin on any part of the body. There were no hairs in the axillæ. The patient was feminine in appearance. Her intellect was equal with that of the peasant women of her native country.

Correspondence.

HYPNOTISM AND ITS PHENOMENA.

To the Editor of the Medical Record.

Sir—Some twenty years ago "Professor" somebody created quite a sensation in this city by a public exhibition of what he termed "electrobiology" or "psychology." At the close of his lecture, which consisted of an explanation of the phenomena that appeared satisfactory to himself, although not in the least accounting for them, he directed all the persons composing the audience to grasp the thumbs of their left hands with two fingers of the right hand, hold them so, close their eyes, and remain motionless. At the end of two or three minutes he stepped to the front of the platform, looked fixedly at the people, called out energetically and in a loud voice, "You cannot open your eyes." Strange to say, quite a considerable proportion of the audience were unable, or at least appeared to be unable to open their eyes. The persons thus affected were taken up to the platform and used by the Professor to illustrate what he had presented in the lecture. He claimed that by proper preparation any individual could become susceptible to the "magnetic" influence, and that for a consideration he would impart his method to any one. The way that he accomplished his object was, to furnish the one he desired to bring under his influence a small silver coin, set in a circular frame of polished metal, on which the person was to look, without taking his eyes off, for a certain number of minutes each day. After a length of time, different in different individuals, he claimed that any one would become a subject.

Having witnessed his exhibition, and being thoroughly satisfied that the phenomena he showed were genuine, I resolved to experiment myself, and soon found that I could produce results similar to those of the "professor." In a short time I had some ten persons under observation, most of them excellent subjects.

Although I was able to demonstrate the reality of the manifestations perfectly, to my own satisfaction, almost every effort to engage others in an attempt to study them was repulsed with a hint that I was over credulous and was deceived.

Although several writers, some of them able scientists, had turned their attention to the subject, and published their observations, yet it seemed but little known by physicians generally. There is but little doubt that it was fairly understood by the ancients, and for several centuries there has been mention made of peculiar psychical conditions that have without doubt been the same as those alluded to. Quite recently, under the name of *hypnotism*, it has been brought forward by Charcot and others, and is now fairly before the scientific world for investigation.

Some of the observations made by myself on the individuals whom I was able to hypnotize, I think, may be of sufficient value to publish.

The most perfect subject was a boy about ten years of age. The method I employed with him was to take his left hand in my right, press the palm between my two fingers and thumb, and then look steadfastly into his eyes for about three minutes. At the end of that time I closed his eyelids, pressed my thumb on his forehead, and in a confident voice told him he could not open his eyes.

He was quite unable to open them. Then, on telling him that his eyes were all right, his power over them instantly returned. Without further manipulations I informed him that he could walk to a certain line on the floor but that he could not cross it. He would walk easily to the line, but he was utterly unable to pass over it, and in the same way, I could make him walk or run, twirl his hands, or execute any other movement that I might order, and he would continue it till I told him to stop. All this time his mind appeared to be quite unaffected. Being an excellent subject he soon passed into what I should call a second stage. This is, without doubt, only a more profound state of the first condition. While in this state he was both mentally and physically under my control.

I might indicate to him that he was some other individual than himself, and he would immediately suppose himself to be that individual. For example, if he was addressed as General Kossuth, who at that time was the lion of the city, he would commence a speech, or in some other way act out his conception of Kossuth. He was so easily brought into this state that by catching his eye, even at a distance, I had him under my influence.

A second case was that of a young lady, of about twenty years. She was also an excellent subject. Although of a very diffident nature, and, under ordinary circumstances, impossible to be persuaded to "favor the company with a song," when addressed as Jenny Lind, and asked to sing, would sit down at the piano with all the airs of the great artist and give an aria, undoubtedly fully under the impression that she was the "Swedish nightingale" herself. On one occasion salt was placed in this young lady's mouth and called sugar. She ate it, apparently taking it for sugar, but as soon as she came to herself she found her mouth painful and sore from the action of the salt.

I have never seen any serious or even unpleasant effect follow in persons who have been experimented upon, with one exception. In this case I persuaded a gentleman who was skeptical as to the genuineness of the demonstrations, to make the attempt himself, to bring the subject, a young girl of about fourteen, into this condition.

He pressed her hand, looked into her eyes, etc., as I have described, and in a short time she was fully under the influence. When he perceived that this really was the case, he became alarmed, and endeavored at once to restore her to consciousness. She evidently was affected unpleasantly by his troubled and undecided manner, and soon began to laugh and cry and betray other evidences of an hysterical attack in which she remained about an hour. I advised him to leave the room a few moments, enter in an unconcerned way and speak to her in an easy, natural tone, on some ordinary subject. He did so, when she came to herself instantly, but remained in a somewhat hysterical condition for about half an hour, after which all traces of the trouble had disappeared.

Experiments on these and other persons were continued for about a year. The conclusions arrived at were as follows:

First.—Impressions cannot be communicated to individuals in the hypnotic condition, except through the external senses. The mind of the operator cannot influence that of the subject by a purely mental effort. He must either speak, write, or gesticulate to convey his ideas.

Second.—Remembrance of what has passed, during

the hypnotic state, in the mind of the subject, is very slight, but if he is told to remember any particular thing while so affected, he will recollect it when he awakens.

Third.—Although I pursued the method used by others, I am satisfied that the employment of any means that will induce a temporary abstraction of the mind is all that is required to induce the peculiar condition.

Fourth.—Although the subjects seem to be entirely oblivious to all that is going on, they are not perfectly so. In the case of a young lady, who was told that she was a bird, and thereupon commenced to hop, her dress became disarranged, and, although continuing to hop like a bird, she was careful to keep her dress in its proper condition.

Fifth.—It is not necessary that the operator nor the one operated upon believe in the truth of hypnotism, or the success of the trial. If the necessary conditions are complied with the effect will follow. One case mentioned above proves this to be true.

All the strange psychical conditions under the names of hypnotism, magnetism, braidism, mesmerism, trance, somnambulism, ecstacy, etc., come under the same category, and I believe that clairvoyance and spiritualism can be included in the list.

As far as I have seen, I have never observed contraction of muscles, areas of hyperæsthesia, or other disorder of sensibility, or any unnatural condition or action of any part of the body in the persons affected, unless the operator should direct their attention to themselves by speaking or motioning to them; for example, he would indicate that their faces were away, that their arms or fingers were stiff, or that they had a pain in the head, back, or some other part. In such a case what was told them would be the basis on which they would feel or act.

If I should venture an explanation, or more properly a description of the phenomena of hypnotism, I would say that they resulted from a suspension of function of the centre for ideas in the brain of the subject, and also of his will, while the infra-cortical ganglia remain free to act from a reflex excitation imparted by the voice, gestures, or manners of the operator.

WOOSTER BEACH, M.D.

105 EAST EIGHTY-NINTH STREET.

LIME WATER IN DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—From Dr. Billington's letter you printed on page 50–52, I learn the following facts, viz.:

First.—That the doctor and I do not agree in regard to the efficacy of lime-water in diphtheria. This I deplore.

Second.—That he objects to my speaking of "our treatment." In regard to that I shall simply say that I was so far from trying to detract from the merit of his efforts, that, instead of insisting on his merely carrying out my suggestions as to the treatment of diphtheria, I meant to speak complimentarily of him. As for the publishing of formulas, I am not in the habit of believing the members of the profession to be unable to write their own prescriptions after they have been advised what to administer, and how often. In regard to priority, I refer you to the paper published by me in the February number, 1875, of the *Journal of Obstetrics*, etc., and the doctor's subsequent papers on the same subject. As you have eyes, you will see.

To conclude, I have neither the leisure nor the inclination to concoct long letters. The profession, after reading papers, need not be told of their virtues in epistolary postscripts. There is nothing "remarkable," therefore, in my "long delay" in answering the doctor's last year's letter. I never intended to speak of or for myself. Art is too long, work too hard, and life too short to spend it in idle quarrels over priority or offended self-esteem.

Very respectfully yours,

DR. A. JACOBI.

PARACENTESIS OF THE PERICARDIUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In the MEDICAL RECORD of December 11th an article appears from Prof. J. B. Roberts, of Philadelphia, putting considerable stress upon a quasi-successful case of "Paracentesis of the Pericardium" that occurred down in North Carolina last July. That, Dr. R. says, numbers twelve (12) in this country, as far as reports now lead him on that subject. I wish to report you a case briefly that was in the hands of Dr. Clemons, of this city, a few months since, and reported at the last meeting of the Erie County Medical Society. We will count this case number thirteen, if you please.

In reporting a case of this kind, it may be useless to enter into many details, whether white or black, married or not, weight, height, etc., as is the custom of many, but give you brief facts in a practical point of view. The author says: "I have in several instances aspirated the pericardium in dropsy of the heart sack, one of which was successful so far as the accumulation in the pericardium was concerned, but as the patient was suffering from incurable Bright's disease, there could be no extended or satisfactory test of the benefit in the operation only so far as it relieved the distressing symptoms of dyspnœa, which proved to be instantaneous and permanent. The operation in nearly all cases, generally speaking, is simple, and may be considered harmless. Many physicians look upon perforation of the pericardium as one of the 'dreaded realities,' and it may be within keeping of this paper to state how the operation may easily be done. In the above case, seven and a half ounces of liquid were withdrawn. The fifth intercostal space is usually selected to puncture, as it is nearer the apex of the heart, but this will be modified somewhat by the amount of distention of the pericardium. (The hypodermic needle frequently answers every purpose, providing the needle is large enough.) The puncture should be made about two and a quarter inches from the left border of the sternum, thus avoiding the internal mammary artery and its distributions. Of course, first see that your syringe is in good working order.

"After carrying the needle slowly inward and upward to the extent of half an inch (your patient in the same recumbent position), set the instrument so that the suction shall extend to the point of the needle, and cautiously carry the needle obliquely upward and inward, watching closely for the moment when the fluid shall appear in the glass tube. It is well to remember that in proportion as the fluid is evacuated the walls of the heart draw nearer the point of the needle, hence it would be a timely precaution, at the moment, to withdraw the instrument slightly. On account of the effusion in the part round about it is sometimes difficult to trace the intercostal space as readily as might be wished, and the

greater danger that could result from this condition of things is plunging the needle into the costal cartilage and thus obstructing the channel in the needle. In the second case the operator was positive the point of the needle came in contact and touched the heart itself. At this time a No. 1 needle was used, and not meeting with the expectant fluid the needle was slowly crowded forward and inward until a peculiar rhythmic movement at the end of the needle was felt, in short, cardiosysophic in its character, and a thread of bright clear blood passed through into the glass barrel of the instrument. It is not for a moment preposterous in any one to ask the result of an unintentional operation of this kind. So far as this case is concerned there was not a symptom manifested from the accident that even broached threatening danger. The case (patient) finally, in due course of time, succumbed to hypertrophy without pericarditis. To say the least, the above case was neither improved or materially worsed by the operation of puncturing."

W. R. Page, M.D.,
Sec. Erie Co. Medical Society.

Sandusky, O., January, 1880.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 2, 1881, to January 8, 1881.

Baily, E. I., Lieut. Col. and Surgeon. Granted leave of absence for two months. S. O. 277, A. G. O., December 30, 1880.

White, C. B., Major and Surgeon. Relieved from the duty assigned him in S. O. 229, October 25, 1880, from A. G. O., and to report to the Surgeon-General. S. O. 276, A. G. O., December 29, 1880.

Williams, J. W., Major and Surgeon. To report to the commanding officer, Department of Arkansas, for assignment to duty, temporarily, as medical director of that department. S. O. 2, A. G. O., January 5, 1881.

Brown, J. M., Capt. and Asst. Surgeon. The leave of absence granted him in S. O. 264, December 2, 1880, Department of the Missouri, is extended three months. S. O. 2, C. S., A. G. O.

Carter, W. F., 1st Lieut. and Asst. Surgeon. Granted leave of absence for one month, with permission to leave the department. S. O. 265, Department of Texas, December 28, 1880.

Abolishing Coroners.—At a recent meeting of the Medico-Legal Society, Mr. Clark Bell read a paper in which he advocated the entire abolition of the system of coroners. He sustained his position by an elaborate argument, in which he showed the superiority of the German method of administering the functions now assigned to the coroner.

Election of Officers of the New York Academy of Medicine.—At the stated meeting of the Academy, held January 7th, the following officers were elected: *President*—Dr. Fordyce Barker; *Vice-President*—Dr. Robert F. Weir; *Trustee*—Dr. S. T. Hubbard; *Member of Committee on Admission*—Dr. J. H. Emerson; *Member of Committee on Education*—Dr. C. C. Lee; *Member of Committee on Ethics*—Dr. V. P. Gibney; *Member of Committee on Library*—Dr. C. S. Bull. The library of the academy now contains over 17,000 volumes, and receives regularly 122 American and European medical journals. Mr. John Jacob Astor has recently given $500 for the improvement of the journal and circulating department of the library.

Dr. E. M. Wight, of Chattanooga, Tenn., forty years old, died of pneumonia, January 6th. He was a member of the Tennessee State Board of Health, Inspector of the National Board of Health in 1879, and enjoyed a wide reputation in the South as a physician and politician. He was the Republican candidate for Governor in 1878, and for two terms was Mayor of Chattanooga.

Dr. George Ford, who has for over thirty years been connected with the State Emigrant Refuge and Hospital, on Ward's Island, died at his residence, on the island, January 7th, of gastritis. Dr. Ford was born in County Leitrim, Ireland, in 1812. He graduated from the Royal College of Surgeons in London in 1837, and came to this country in 1849. He received the honorary degree of Doctor of Medicine from the old New York Medical College. He had been connected with the Emigrant Hospital almost since his arrival in America, at first as a resident physician, and at one time as visiting physician. He was appointed the assistant physician in 1855, and so remained until six years later, when he became the Physician-in-Chief, which position he filled with recognized ability up to the time of his death. He married in Ireland a niece of Felix Ingoldsby, formerly well known in this city, and leaves seven children. Dr. Ford was a member of the County Medical Society and of the Pathological Society, as well as of the Society for the Relief of the Widows and Orphans of Medical Men, and of the Friendly Sons of St. Patrick. He was a man of very retired habits, attending strictly and conscientiously to the duties of his office, to which he gave his whole time.

Dr. L. P. Yandell has retired from the editorial management of the *Louisville Medical News*. Dr. R. O. Cowling will continue as sole editor of that sprightly and wide-awake journal.

Bequest to Yale Medical College.—The late Dr. David P. Smith, Professor of Surgery in Yale Medical School, whose recent death has been so widely lamented, bequeathed to the Yale Medical College all his professional library and instruments, also two-fifths of all his property. This last sum is to be used in the endowment of the Chair of Theory and Practice of Medicine.

MEDICAL CERTIFICATE WRITING.—A correspondent on Murray Hill sends us the following amusing hit on medical certificates: "I am a constant reader of your most valuable journal. I see it almost every week—at some friend's office. It is an excellent medical journal, the best in the country, and deserves the liberal support which we all give it, either by subscribing to, or reading it.

"I will state my case briefly: I have a young friend—a rising young man—not in the baking-powder, drug, or wine business, I am sorry to say; in case he had been, then I would have a precedent to go by. My young friend has invented a trap—a rat-trap—a most extraordinary contrivance, sure catch every time. It retails at fifty cents; wholesale, twenty-five cents. A liberal reduction made to ministers and their families. Although not yet fairly in the market, over a hundred ministers have given certificates as to its wonderful working. My friend lacks capital to freely put the article before the public; he offered me a partnership provided I furnished the money. On the matter of business I believe the Code of Ethics is very explicit—if it is not the spirit is against it, and that is what we are all after just now, I understand. The partnership I did not seriously entertain, partially because I have not just now the ready money—and of course on account of the code. It struck me that my professional reputation being somewhat enviable, that I could give character to his trap enterprise by a suitable certificate. I know I could conscientiously write such a certificate and testify to the fact that it is an entirely original invention, that my friend is perfectly trustworthy in everything he says, and that I know the iron of which it is made comes from Sweden and is the purest in the market. Also, that no rat has as yet escaped from its jaws. The only objection to all this is, that my motives might be impugned, as he would send the circulars everywhere for the good of householders in general, and our committee on ethics would write me a note. Still, I am proud to believe that the reputation of the profession is safe in my hands, and my position would secure me from petty persecution. But I desire to do what is right, nevertheless. It cannot be said that the trap is 'any patented instrument intended for medical or surgical use.' Neither is it a 'drug, nostrum, mineral water, wine, or other proprietary article intended to be used as a nostrum or remedy in disease.' Hence, I believe I am beyond the reach of the code at least, and I wish to think so in the interest of a really useful invention."

THE WALNUT HILL ASYLUM, AT HARTFORD, CONN., for the treatment of inebriates and opium-takers, has been reorganized, and is now open for the reception of patients as a private institution, with full legal powers, and on the basis of a first-class family home. Only a limited number of patients are received, each one receiving direct personal care and treatment. The former superintendent, Dr. T. D. Crothers, will have the full charge.

SUMMARY OF 2,247 CASES OF ACCOUCHEMENT, FROM JUNE 8, 1819, TO MAY 1, 1879.—At a recent meeting of the Greene Co. (N. Y.) Medical Society, Dr. J. B. Cowles, of Durham, Greene Co., N. Y., presented the following summary of his obstetric experience for the past sixty years: Whole number of cases, 2,247; premature cases, 63; males, 1,153; females, 1,094; twins, 26—males 10, females 10, male and female, 6; delivered by forceps, 14, three children died; craniotomy, 4; face-presentation, 4, two children died; placenta previa, 4; adherent placenta, 4; monsters, 2, both died; deranged development, 4; convulsions, 5, all died; foot presentation, 40, four children died; breach-presentation, 5; shoulder-presentation, 3, one died; arm- and hand-presentation, 4, one died; both hands, 2; funis-presentation, 4, one died; imperforate anus, 1, died. All other cases, natural or head-presentation, not interfered with particularly.

Dr. C. presents the following conclusions: Cases of placenta previa relieved as soon as possible by the use of ergot and plugging of the vagina. In adherent placenta, if natural efforts do not soon relieve, introduce the hand after ergot is administered, and detach with care. If hemorrhage supervene after the extraction of placenta, I excite action by pressure externally, and internal manipulation, until the normal action is restored. In treating all cases of convulsions of seven months, bleeding in the arm and antispasmodics give relief. These cases resemble hysteria epileptica. Three cases of convulsions were due to puerperal apoplexy. These were relieved by opening the "temporal artery," and labor came on in one hour, and consciousness returned. All had been bled previously in the arm, twenty-four hours before, without relief. Of the cases of monstrosity, in one of them the left limb looked like an amputated stump, at the lower third of the thigh, one hand attached to the forehead, the head, a mere sack of fluid occupying the left side of the neck. The other case had the appearance of having the lower viscera pressed out above and below the pubes. I relate this case as peculiar, from the history of the mother. While milking, the cow trod upon a chicken and pressed out the viscera, the child, when born, resembled the chicken. The mother was enciente about three months when this accident took place. (Query.) Did the effect upon the mind produce the results? The case of imperforate anus was that of a male. Two cases of kyllosis, one case, foot turned in; the other case, foot turned out. Two cases of hare-lip, one of these a deficient os palati and vomer; child died very soon. In the other case operation was successful. One case of twins at seven months. Labor was superinduced by tapping for dropsy of amnois, in which thirty-six pounds of fluid escaped, which afforded relief; one child lived eight days, the other forty-eight hours. The other case, in which it had become necessary to relieve twice, by craniotomy, on account of contracted pelvis, in order to relieve the anxiety of the mother, and hoping at the end of seven months the child might live. One child lived five weeks, the other but a few days. In this last case the woman died in child-birth, having fallen into unskilful hands. In all cases except head- and face-presentations, I have pursued podalic version with satisfactory results.

ON FALSE HEARING AND AUTOPHONY IN SINGERS, SPEAKERS, AND PERFORMERS ON CERTAIN MUSICAL INSTRUMENTS.

By SAMUEL SEXTON, M.D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

(Read before the New York Academy of Medicine, January 6, 1881.)

Mr. President and Fellows of the New York Academy of Medicine:

Musical people, speakers, and others, when affected with certain aural diseases, are thereby frequently incapacitated for their pursuits. Under such circumstances, however, the aurist is not always consulted, but the advice of the general practitioner is sought for fancied ailments, in which the ear's disease is not always considered a factor. The defects in hearing that are found to exist in these cases arise from diseases that are more or less familiar to every practitioner, but it seems to the writer that clearer definitions are desirable in order that more effective treatment may prevail.

The anomalies of hearing are conveniently separable into two groups: 1, defects that pertain to sounds produced and heard by the patient himself, *e.g.*, his own voice, the notes of a cornet upon which he plays, etc.; 2, defects that pertain to sounds heard by the patient in the natural way; these are such as strike the ear in daily life, as the voices of others, etc. The first class refers to false hearing, the second class to hardness of hearing. The former of these has the greater interest for us here. Before going into the subject, however, it would be well to have a clear meaning of the terms false-hearing and autophony, as understood by otologists. Autophony signifies in this connection the hearing of one's own voice, while speaking, as though it failed of utterance in the usual manner, and passed directly to the speaker's ear from within the head.

The definition of pseudacousma (false hearing), which I shall use, may not be assented to by all, but it is the best I can give under the circumstances. The person, from some affection of the ears, fails to hear his own voice in the usual manner; it does not appear to issue forth from his mouth, and then come around and strike his ear-drums, but instead gains access to the nerve of hearing by traversing the tissues between the mouth and ears in a more or less direct line, thus being heard *false* as compared to normal hearing; it is false both as regards pitch and timbre. Sometimes both ears are affected in this manner, but if the disease is confined to one of them he then receives the normal sound impression in the usual way in one ear, and the perverted impression in the other ear. In a certain number of cases, owing probably to some peculiar resonance in the tympanum or its connections, there is heard what is well described as an "echo" after each word spoken.

These phenomena are frequently ascribed by the patient to some throat affection which is supposed to modify the voice, even after repeated assurances that the vocal organs are healthy.

Although this disability cannot be experienced without distress by any musical person, yet it is probable that none suffer so much in this way as singers, for even a simple cold in the head may give origin to false hearing, not from the physical disability as regards the throat, but from the autophonous voice that so frequently accompanies the "stuffiness" in the ears then experienced. This condition must not be confounded with the simple nasal tone acquired by reason of a stoppage of the nasal passages from any cause, for in this state the patient's voice sounds alike, both to himself and others.

False hearing may be experienced at any age. It usually announces itself suddenly in the course of acute aural affections, and after a longer or shorter duration takes its departure as quickly as it appeared. In the more chronic cases, however, it comes on more slowly and is more persistent. In all acute cases there is more or less false hearing at some period of the attack.

When the subject of false hearing performs on certain musical instruments, especially upon the violin or the cornet—instruments held in contact with the face or lips when played upon—he finds that sonorous vibrations appear to fail to issue forth from the instrument, that, like autophonous voice, they are by him only recognized as resounding within the head.

With this brief and somewhat imperfect explanation of the phenomena to be touched upon I shall proceed to introduce from my note-books some illustrative cases which, I trust, may aid in throwing light upon the subject. These cases are divested of such details as would be without particular interest in this connection, an omission that includes the examinations made with the tuning-fork, König's rods, organ-pipes, the voice, and such other means as are usually employed to determine defects of the auditory nerve, and the condition of the transmitting mechanism of the middle ear. The vocalists are, for convenience, arranged in one group, and in another the performers on musical instruments.

CLASS I.—VOCALISTS.

Case I.—This is a singer, fifty-two years of age who consulted me in May, 1879, for an acute purulent inflammation of the left middle ear which had been greatly aggravated by the ill-advised use of an irritant lotion. There was deafness to ordinary sounds, and in speaking he experienced autophony; when he attempted to sing in the church choir to which he belonged, he was unable to strike the correct pitch, his voice sounding unnatural to him; when he sang, his notes were a "confused jumble," as he himself expressed it. This case proved to be a very grave one, and the permanent injury to the conductive mechanism prevented an entire cure as regards the autophony. After his entire recovery from all inflammation, which took place in about a month, the autophony yet remained in some degree: he could, however, remove the symptoms by pulling the tragus firmly outward and downward.

Case II.—This patient, a lady thirty-four years of age, came to my office in September, 1880, with chronic catarrhal inflammation of both middle ears. The disease was of several years' standing, and since it was first noticed until the present time there has been a gradual increase in the deafness, and she can now only hear loud conversation. For two years past she has been unable to sing without hearing the sound of her voice most unpleasantly in her ears; however great her efforts, the notes appear to die away without utterance. Her voice is a very good one, as I can testify from hearing it, but she sings

without any confidence in her own power. She hears conversation best when in a rumbling conveyance, or when on a noisy street. She is still under treatment.

Case III.—Is a gentleman forty-six years of age, who, while suffering from an itching of the external auditory meatus, was advised to drop into the ear a weak solution of carbolic acid. By mistake he prepared a mixture of equal parts of concentrated carbolic acid and glycerine, a drop or two of which was put into the left ear. He instantly experienced pains of a most excruciating character, and although water was at once instilled into the ear to dilute the mixture, perforation of the drum-head ensued and acute purulent inflammation of the middle ear was established. The accident that gave rise to these unpleasant symptoms occurred in February, 1878, and owing to the patient's run-down condition, it was nearly twelve months before recovery took place. Throughout the attack the voice was autophonous, as regards the left ear—a symptom that annoyed the patient very much, for he had a musical voice, and, before the attack, derived much pleasure in singing duets with his wife at social gatherings; owing to the autophony, however, his voice seemed flat—to himself it was about half a note low. He was very sure, at first, that the throat was in some way involved in the difficulty; an explanation of the phenomena, however, corrected his mistake. When the ear was cured the ability to use the voice in singing returned.

Case IV.—A leader of a church choir. He is forty-three years of age. This patient consulted me in September, 1878, for a subacute catarrhal inflammation of both middle ears, engrafted upon a chronic catarrhal inflammation of long duration. The subacute attack was attributed to a severe cold. There was autophonous voice in both ears, but in the right one it was occasionally absent. When speaking or singing the voice seemed to strike the ears, especially the left one, most unpleasantly—the words failing, as he fancied, to find utterance from the mouth. The autophony sometimes alternated from one ear to the other, and it was more or less intermittent in both of them. His attempts to sing with the choir were the cause of both astonishment and amusement to the auditors, and as for himself, he was utterly discomfited by the misfortune, and sorrowfully acknowledged that his "voice was out of tune." Although unable to sing with others, when he came to my office he heard correctly the notes of a hand-organ in the street, which was at that moment playing a selection from Trovatore. Entire recovery did not take place in the three months that he remained under my observation.

Case V.—This patient was a commercial traveller, thirty-four years of age. He was first seen by me in April, 1879, at which time he believed himself to have some throat trouble. A careful examination of the vocal organs had been made before he was sent to me, but all assurances of their healthfulness failed to entirely convince him that the difficulty was elsewhere. An examination, now made by myself, showed that there was chronic catarrhal inflammation of both ears, evidently of long standing. The voice, he informed me, had been autophonous for three years, and it sounded so disagreeably that he was unable to sustain vocal efforts long at a time. In consequence of this disability he lost his situation, and for a short time before consulting me his precarious livelihood depended on his exertions as a canvasser. Whenever the autophony came on—it was intermittent—all business had to be put aside for a time, and some attacks, when the mental depression was great, lasted for hours. These attacks came on quite suddenly, were characterized by most distressing roaring in the ears, which was increased by every attempt to use the voice. The mental condition seemed to favor palpitation of the heart, and altogether, the attacks left him exhausted for a time and incapacitated for work. The tinnitus aurium and autophony were the cause of great deafness, but when absent the hearing was good. This patient assured me that he had frequently thought that suicide would be preferable to the distress he had to endure. My first effort in this case was to convince the patient that the anomalies experienced in no way prognosticated danger to life, and an absence of dread has been followed by almost entire relief as regards the severe paroxysms described.

CLASS II.—PERFORMERS ON MUSICAL INSTRUMENTS.

Case VI.—A teacher of music, sixty-seven years old, consulted me in March, 1879, for an acute purulent inflammation of the left middle ear. The attack was ushered in with very severe pains and tinnitus aurium in the ear, and the patient was soon dismayed to find that when he attempted to play upon the violin its notes were, to himself, anything but musical; in fact, the favorite instrument that had never failed to respond in rhythmical sympathy to his cultivated touch, now sent forth noisy discordant sounds only. He also discovered, much to his astonishment, that his voice was autophonous. The false hearing, both for the voice and for the violin, was confined to the left ear, and inquiries elicited the fact that the strange conduct of his violin only manifested itself when held against the left cheek while played upon, for when it was held away from the face its tones were heard in the usual way. Normal hearing returned on his recovery from the aural disease, which was in about three months from the beginning of the attack.

Case VII.—This patient performs on a cornet in a small orchestra; he is thirty-five years old. He came to me in January, 1879, while he was suffering with an acute purulent inflammation of the left middle ear; in this ear he was deaf to ordinary voice. When he plays on the cornet he fancies that no sound issues forth from the instrument, but that from his lips the vibrations go back to the left ear, from which they resound again most unpleasantly. When attempting to play upon his cornet with the orchestra it seems, to himself, to be pitched a quarter of a note higher than the other instruments, and when he lowers the pitch to that of the orchestra he is told that he plays too low. After several futile attempts to play in tune he was obliged to throw up his engagement. A violin played upon while resting against the left cheek, sounds more loudly tl an if heard in the natural manner. The effect of orchestral music on the affected ear was peculiar—it seemed to be "damped." The cornet's tones, for example, sounded like that instrument when the "mute" is used. The music, however, was distinguished, unless low tones, which were first imparted to the floor before reaching his ear through the body, had the effect to confuse his perception in some degree. By placing his hands on a piano, while the cords were in a state of vibration, the sound was carried to the affected ear through the tissues of the body. This patient's voice was autophonous. His recovery from the severe aural affection was slow; a cure, however, was effected in three or four months, and it was then found that he had not been permanently incapacitated, inasmuch as he resumed his former place in the orchestra.

The transmission of sound, under certain circumstances, through the tissues of the body to an ear affected by disease, is of frequent occurrence. Patients not infrequently complain of the unpleasant sensation thus experienced by hearing their own footsteps on the pavement, or the heavy rumbling sounds of the street.

Case VIII.—This patient is likewise a cornet-player. His age is fifty-three years. I first saw him in September, 1880, three weeks after he had contracted a severe cold from exposure one stormy night in going home from a performance. A few days after the exposure there was deafness in the left ear, and he could not hear conversation spoken in a low tone. Examination showed an acute catarrhal inflammation of the middle ear. I found that he was deaf to the notes of the highest organ-pipe. When he plays upon the cornet the whole volume of sound seems, to himself, to pass backward and escape out of his head through the left ear. He has autophonous voice.

The attack in this instance was a mild one, and the patient resumed his place in the orchestra in about a week after he first came under my observation.

This patient could play upon the violin, and from an experiment made during the aural attack it was found that this instrument was heard false, the phenomena experienced being the same as were reported by the previous patient under very similar conditions.

Case IX.—This patient, a teacher of music, aged forty-one years, was sent to me by a medical friend in October, 1879. His deafness was very great; he hears words only when shouted directly into his ears. For the past eleven years he has suffered greatly from both autophony and tinnitus aurium. The cause of these most unpleasant symptoms is chronic catarrhal inflammation of both the middle ears. He has become exceedingly nervous and irrascible, and his manners make his family as wretched as himself. Thoughts of putting an end to his life are constantly in his mind. He informs me that since his sufferings began he has been under the treatment of nearly every prominent aurist in this country and in Germany, besides many general practitioners, but without benefit from any; indeed, it is to be feared that his sufferings have been increased by the frequent inflations to which the drums have been subjected by the Politzer method. Before he had any serious disease of the ears he played upon several musical instruments, but their sounds to him are now tormenting. His wife tells me that he is most of the time "wild with nervousness," that the noises in the head, when the voice is most autophonous, convince him that he must be possessed of some serious ailment. Frequently he refers to his throat as the seat of some disease. For several years past he has devoted whatever strength and means remain subject to his control to travelling about in search of relief. This patient was benefited by the use of cotton-wool pellets, adjusted to the relaxed conductive mechanism, but he was unable to keep them in place very long without causing irritation of the drum-head.

Case X.—This girl is now receiving musical instruction on the piano. She is thirteen years old and has a talent for music. She was brought to me in November, 1878, while suffering with acute catarrhal inflammation of both middle ears, caused in part by reflected dental irritation. The right ear was most affected, but the voice was autophonous in both. With the autophonous voice in the right ear she describes the sound of the voice as remaining there a perceptible period of time and having a timbre resembling a vibrating piano cord. The piano, heard at a distance, sounds damped, but is not unmusical. All of her efforts to perform on the instrument are unsatisfactory, for the sounds reaching the ear by tissue-conduction—through the body—are heard false, and create an unpleasant and discordant jangle. A good recovery was made in about two months, when she resumed her musical instruction. The hearing, which of course had been imperfect, was entirely restored.

Case XI.—The patient is an organ-tuner, aged twenty-three years. His hearing was always good until three weeks before consulting me, in September, 1879. He now had an acute purulent inflammation of the right middle ear. In this ear he cannot hear ordinary conversation. In the other ear the hearing is good. There is autophony and tinnitus in the affected ear. He is unable to tune an organ, for when he blows the tuning-pipe its sounds seem to be within the head; and furthermore, the beats above upper F are indistinguishable, unless the ear is close to the pipe. Normal hearing was restored after five weeks' treatment.

REMARKS AND CONCLUDING SUMMARY.

From a careful study of false hearing in these cases, and many others, I am led to believe that the causative lesions are mostly to be found in the middle ear—the conductive mechanism failing to transmit sound to the auditory nerve in the normal manner. The pathological lesions here concerned permit of great variety in the manifestations of the phenomena in different patients, since in some instances a careful examination of the ear fails to bring to light scarcely any change in the conductive mechanism, while in others but vestiges only of these structures remain. The particular abnormity, however, would seem to be some structural change that gives rise to interruptions in the normal tension of the ossicular chain. Such interruptions would occur from luxations of the malleo-incudal or incudo-stapedial joints, or from other displacements that disease might cause to the ossicles. When defects of this kind exist other influences affect the character of the false hearing experienced. Thus a relaxed drum-head, by its greater freedom of motion, increases the frequency of autophonous experiences; or the presence of air, fluid, or any product of acute or chronic inflammation in the ear will modify the resonance of the tympanum. Next in importance to the changes in the ossicula as a causative abnormity, is the movable drum-head which, indeed, is the essential agency in causing the interruptions that occur in pseudacousma; for, so long as a certain tension in the ossicular chain remains, the drum-head may be greatly relaxed, suffer much loss of substance by perforative inflammation, or become thickened and loaded with opacities, without causing false hearing. In fact, good hearing often remains notwithstanding such changes. As regards this view, I am aware that other authorities trace the origin of many of these phenomena to affections of the inner ear, and I am free to confess that a decisive conclusion, in which all shall agree, will not be reached until those who have the opportunity shall have given more time and attention to both the physiology and pathology of this subject.

My own experience, so far, has been mainly in the clinical study of the pathology of middle-ear disease, and if it is thought that in the cases I have pre-

sented the differentiation was not in all cases warranted by the symptoms, it may be said in reply that absolute certainty in diagnosis is not possible until our knowledge of the physiological functions of the terminal filaments of the auditory nerve has a more substantial foundation than theory alone. Otologists have given, however, no little attention to this subject, especially in the past ten years. Prominent among these, Roosa, in his work on the ear, and Knapp, in a paper in the second volume of the "Archives of Ophthalmology and Otology," express the belief that the cochlea is the seat of lesion in a certain number, if not all, of the cases under discussion; while Burnett, in his treatise on the ear, maintains that the phenomena of autophony—which he describes as "an altered resonance of the voice"—are caused by an abnormal condition of the Eustachian tube, which gives rise to undue intratympanic air pressure. Brunner, who describes an interesting case in the second volume of the "Archives of Ophthalmology and Otology," part first, page 107, entertains the opinion that autophony is a resonance from "a vibration of the air in the middle ear, shut in by the closure of the tubes."

The conclusions of the two first-named observers were, in good part at least, drawn from the interpretations of patients, whose psendacousma was tested by the notes of musical instruments, while the experiences of the two last mentioned otologists were confined to their patient's autophonous voice. I cannot but believe that if the observers first alluded to had kept in mind the fact that vibrations from musical instruments could reach the ear, in the instances cited, in the same manner the voice does when autophonous, their conclusions might have been different.

My own opinion as regards the *modus operandi* of the production of false hearing, is, that in the diseases where it occurs the ear fails to take cognizance in the normal manner of sounds that reach it through the surrounding air; the conductive mechanism not only failing in a greater or less degree to transmit such sounds to the auditory nerve, but permitting sounds within the body, usually inaudible, to be heard. Thus, in psendacousma the sounds of the voice, or of the cornet, are transmitted in a more or less direct course through the intervening tissues from the mouth to the ear, to be heard, so to speak, from within the head. Undulations of sound in speaking, singing, or playing upon the cornet, are, of course, always transmitted to the ears through the intervening tissues, as well as by the air, but in the normal state of the transmitting mechanism the former are excluded; otherwise, there would be confusion from interference. Even if these media transmitted sound from the mouth to the ears with equal velocity, confusion would still ensue, for the ear would be unable to harmonize the undulations received in both a normal and abnormal manner at the same time—the one through the air, the other through the tissues. A patient who experiences autophony, finds it a difficult matter to locate the precise source of his own voice, as it approaches the ear from an unfamiliar source; this experience, moreover, seems to vary in different patients, some locating it in the ear itself, others in various regions of the head. A lady, for example, who suffered with autophony, informed me that her voice seemed to go out of the back of her head, and she fancied it was heard by those standing behind her only. To some the vocal intonation is so unfamiliar that it is difficult for them to believe that the voice is not spoken by another, and that the speaker is at a distance, or in a different apartment. In certain instances the patients describe the voice as remaining in the ear a perceptible period of time, or as echoing in the head; these are experiences most confusing, inasmuch as they give rise to the sensation of the head being "empty," or "hollow." Musical people, when experiencing this feature of pseudacousma, either in singing or playing upon certain instruments, likewise find the tones produced lingering in the ear, and seeming to have a different pitch than at their inception.

Patients who experience autophony, are aware that the pitch of the voice has undergone a change; in certain cases it seems lower than natural, and sometimes it is described as hoarse; such patients, when singing or speaking, raise the voice above the natural pitch. On the other hand the voice sounds unusually loud to some individuals, and, in order to avoid disturbing others, they speak in low, or even whispering tones. When autophony is intermittent, the patient will alternately raise and lower the voice during conversation.

The diseases that give rise to false hearing include a large portion of all of those embraced in the nomenclature of otology; a complete list would include nearly all of an intratympanic origin, as well as those located in the external auditory meatus and Eustachian tube, which in any way interfere with the movements of the conductive mechanism. Among the causes sometimes located in the external auditory canal, the most common are diffuse and circumscribed inflammation, the impaction of cerumen or foreign bodies; sometimes a syringeful of water thrown against the drum-head will cause temporary psendacousma.

With the well-known affections of the auditory nerve and its ultimate filaments, in which total deafness usually exists, we have no concern here. That the inner ear, however, is conjointly affected in certain middle-ear diseases, there can be no doubt, but the obscurity of labyrinthine affections, and perhaps their rarity as well, has prevented aural pathologists clearing up the ground as thoroughly as could be desired. It is, therefore, because I have absolutely nothing new to add to the scanty literature of labyrinthine diseases that I have thought best to confine myself to the more common affections of the middle ear, which, after all, have the greatest interest for the profession in general.

The diagnosis of pseudacousma is not always easily made, as the phenomena vary in almost every case, and the patient's description is liable to mislead. Owing to the patient's fancy respecting his changed vocalization, and to the sympathetic cough that so often accompanies aural affections, the patient's throat is likely to receive an undue share of attention; this fact should not be overlooked in any case, but in singers it is important, for obvious reasons, to avoid any influence of this kind in treatment. One important fact should always be kept in mind in cases of false hearing: namely, the phenomena pertain exclusively to sounds that reach the patient's ear through his own tissues. Of course if the patient is so deaf that his own voice does not affect his drum-heads from without, he constantly hears false in a certain sense, but we are here more particularly concerned with that state where the false hearing is, owing to intermissions in the ossicle's tension, of a variable character. Such intermittent pseudacousma is common during acute inflammation of the middle-ear, especially when the case is recovering, and also

in certain chronic catarrhal inflammations of the same region. In these cases the patient while singing, reading aloud, speaking, or playing upon certain instruments, may suddenly hear the sounds produced resounding in the head, while he fancies their tone must be quite unnatural to others. These unpleasant symptoms usually disappear, for a time, as suddenly as they came, and the deafness for external sounds, which always exists while the pseudacousma lasts, also disappears. The interruptions vary in their duration from a few seconds to days or even months.

A very slight cause, as a cold in the head, may so disarrange the conductive mechanism that a singer's voice becomes false to an incapacitating degree, and while the pseudacousma exists he cannot pitch his voice to the same tone with other singers or with an orchestra, because he hears his own voice in a false tone as compared to the accompanying tones which he hears with greater or less distinctness. A similar difficulty in keeping in tune is experienced by performers on certain musical instruments. When the conductive mechanism is subject to frequent alternations of tension in these cases, as when the membrana tympani is greatly relaxed, the rapid changes from true to false hearing are exceedingly distressing.

Deafness, unattended by pseudacousma, although not always preventing correct singing or hearing of musical tones, if very great in degree, practically unfits any one from engaging in professional musical pursuits; a singer will under these circumstances sing so loudly and play the accompaniment on a piano so heavily that it is positively painful to hear his performance, although he sings and plays in tune.

Some musical people, when affected with pseudacousma, cannot endure the sounds of music, for at one moment its strains strike on the ear with a pleasing effect, and at the next they seem muffled: at the same time certain notes, especially the lower ones, may be heard through the body.

There are some anomalies of hearing, that, to a thorough knowledge of this subject, should be alluded to, although not classified with false hearing; the following are examples: A gentleman contracted from sea-bathing an otitis media serosa of the right side. The external auditory canals were large, and in diving, water was freely admitted to the drum-heads, the right one, on examination, being found moderately hyperæmic. The tympanic cavity contained a considerable quantity of serous fluid, which could be observed to change its position whenever the patient moved his head. When the drum was inflated with air by Valsalva's method the fluid was thrown into bubbles which lined the whole inner surface of the membrane. As he suffered but little pain or deafness from this attack I was not consulted until the fifth day after getting the sea-water in his ears; it was at this date the above observations were made. His voice was now autophonous, and his footsteps jarred very plainly on the right ear. He could hear a low tone of voice in both ears, but the highest pipe of the organ could not be heard in the affected ear. This gentleman, who is a Long Islander, when a boy, sometimes followed the hounds. It was then well known to all of the hunt that he could hear the dogs better than others; in fact, even after all the rest had ceased to hear them, if the party kept quiet he could hear their deep notes and also indicate the direction from whence they came. He related to me another interesting experience that illustrates his wonderful capacity to distinguish low tones: When boating in the Great South Bay a few years ago with some friends, he heard the low peals of thunder that accompanied the sheet lightning then attracting their attention, a phenomenon which was inaudible to all of the party but himself; his companions were aware of the flashing only. His recovery from the otitis media serosa was rapid and complete.

A case reported by Dr. Charles H. Burnett in the "Transactions of the American Otological Society," vol. i., p. 106, is also of interest. The patient was a young lady, of musical acquirements, who had good hearing except for low tones like the bass notes of an organ, or thunder; as regards the latter "she first became aware of her deficiency while walking in the fields with her father, for the latter could distinctly hear the thunder of an approaching storm" while "she could hear nothing of the kind." Dr. Burnett does not report any peculiarity in the auditory apparatus in this interesting case. In my own case above noted the drum-membranes were among the largest I have ever seen, and slight inflation by Valsalva's method caused bulging of the drum-membrane on both sides of the malleus handle. The flapping membrana tympani seem not to affect the hearing for ordinary sounds, the tension of the chain of ossicles probably remaining intact.

Attention has been called by writers to the fact that in certain cases where deafness exists the patients could hear best the notes of the middle register of the piano. The number of observations having been too few to throw much light on the subject, I determined to institute some experiments on a considerable number of patients at the same time, and as the piano was not considered the best instrument for the purpose, I requested my friend Prof. Mayer, of the Stevens' Institute of Technology, Hoboken, to conduct some experiments with me on the large organ of Dr. Hall's church, which was, some three years ago, kindly placed at our disposal for that purpose. The results of these experiments have not been as yet prepared for publication, but two of the patients whose hearing was tested on that occasion are of interest here: they were both of them women of about forty-five years of age, extremely deaf to conversation from the effects of chronic catarrhal inflammation of the middle ear. Neither of these patients could distinguish the higher notes, but when the *middle register* was reached they could plainly hear the notes sent forth by the organ. Below the middle register these patients heard no sound again until the lower notes were sounded; these were heard by both patients. The experiences of others present on this occasion seemed to confirm the observation respecting the capability of some individuals to hear the middle register best; one of them, a gentlemen of musical education, although hearing all the notes in some degree, found that those of the middle register were heard most distinctly. The following case is another example: A piano-tuner, fifty years of age, who had been thus employed for twenty-five years, gradually became quite deaf; it was finally ascertained that in tuning a piano, after passing above the middle, he began to sharpen up to the end of the scale—in the three octaves he sharpened a fifth. This, of course, did not fail to dissatisfy the customers of the establishment that employed him, and he had to give up his occupation.

Facts like these seem to confirm the physiological theory used in explanation of these anomalies:

namely, that in such cases there must be some pathological change in the cochlea. Inquiries of practical musicians, however, elicit the statement that the cornet or reed stop of the organ is the clearest and most natural in the scale, and, therefore, most easily heard. On the piano, middle C is the equivalent of this, which accounts for its being heard better in certain cases.

It is an interesting fact that sound undergoes a peculiar modification in certain cases of acute inflammation of the middle ear, whereby low, heavy undulations from street trucks, elevated railway carriages and the like, are heard as high in pitch; the causative abnormity existing in these cases has not been, so far as is known to me, satisfactorily explained; that it will be found to lie in the conductive mechanism, however, I do not doubt. These cases are to be distinguished from paracusis acris, where the painfully acute sensibility to sound will be found to depend on other diseases than those of an aural nature; this latter, together with some other symptoms having a close relationship to aural disease, will be discussed in another paper.

The prognosis of pseudacousma in acute affections of the middle ear is usually favorable, as normal hearing is re-established in a very considerable number of cases, and false hearing disappears in nearly all of them. When, however, the anomaly occurs in the course of chronic catarrhal inflammation of the middle ear it is a very persistent symptom. In the cases that arise from dislodged collections of cerumen that impinge on the drum-head, or from foreign bodies, the removal of these is usually sufficient to relieve the patient. With the cure of furuncles or of diffuse inflammation in the external auditory meatus, the result is likewise favorable.

As regards treatment, we can scarcely ever confine ourselves to the treatment of these symptoms alone, and after all pseudacousma is only a symptom that may accompany many aural diseases: any attempt in this direction would, therefore, carry me beyond the scope of this paper.

The successful treatment of any aural disease, however simple its nature may be, often depends on the recognition of the value of the symptoms discussed in this paper, and we should not fail to keep them in mind when considering the management of our cases. The absence or presence of the acoustic symptoms, pseudacousma and tinnitus aurium, is a valuable guide in treatment, although our remedies should meet the physical conditions rather than the acoustic, knowing, as we do, that hearing will generally return when the physical functions assume their wanted sway.

In conclusion, I crave the indulgence of observers with whom I honestly differ on some yet obscure points, trusting that we may by our united efforts leave this subject further advanced than we found it ten or fifteen years ago. My main object in this paper has been to endeavor to present to those of the profession who are engaged in more general professional pursuits, some hints respecting the management of cases daily seen in the practice of medicine, but not always fully understood.

Small-Pox in New York and Philadelphia.—Forty persons died of small-pox in Philadelphia last week, and it is estimated that this mortality was among one hundred and fifty persons suffering from the disease. In New York the disease is traced to Italians or persons from Philadelphia.

THE DISEASES OF JAPAN.

By DUANE B. SIMMONS, M.D.,

DIRECTOR AND SURGEON-IN-CHIEF TO JIEUZEN-IN (GOVERNMENT HOSPITAL) OF YOKOHAMA, ETC., ETC., YOKOHAMA, JAPAN.

The difficulties which oppose themselves to the acquisition of a correct knowledge of the diseases of Oriental nations is much greater than would be supposed, and cannot be appreciated by any one who has never made the attempt. Nearly twenty years' residence in this country, a large consulting practice with the native doctors, and many years' charge of one of the largest of the government hospitals, has given us unusual opportunities, however, for the collection of a mass of facts bearing upon this subject, and forms the basis of the following notes.

It is but justice to ourselves to state here that there are no mortuary records kept by the government of a reliable nature, as not one in ten of the so-called medical men can diagnose any but the most simple diseases. Here, as it is the world over, the greatest mortality is to be found during infantile life. At the head of the list of general causes operative in producing this result here, as elsewhere, is the inability of the poor to give their offsprings proper care, their ignorance of the first principles of hygiene, and, especially in this country, inefficient, and in many cases entire absence of medical treatment.

The influence of a high temperature on the mortality-rate of infants in this country is very pronounced. Diarrhœa and cholera infantum, though common as causes of death, are far less so than affections of the nervous centres terminating in convulsions. We have no means of estimating the mortality from this cause, but are disposed to think it greater than from all others during the summer months. Some explanation for this may be found in the fact that all infants have their heads shaven for the first year, and, tied on the backs of nurses or their elder brothers or sisters, are often exposed to the rays of the sun quite unprotected by any kind of covering.

This exposure of the unprotected shaven heads to the cold in winter gives rise to affections of the respiratory organs, and especially the very fatal one of capillary bronchitis. Hereditary syphilis, both as a direct and predisposing cause of infantile mortality, is undoubtedly very great.

As the milk of animals is not used by the Japanese, there is no good substitute for that of the mother, when poor or insufficient, so that many infants undoubtedly suffer from semi-starvation, thus causing them to fall an easy prey to diseases which the well-nourished are able to withstand. We would observe, however, that a feeble attempt is made to supply the want of milk from animals by the use of malt properly diluted with simple water, or that from long-boiled rice.*

Passing, now, to the diseases of childhood, we find that scarlet fever and cerebro-spinal meningitis have never yet made their appearance in this country. I am aware that this is denied by at least one foreign medical man, in regard to the former, who claims to have seen eight or nine cases of it. But if this is so, how happens it that no one else has observed it? A disease so terribly infectious as scarlet fever could hardly be limited to the practice of one individual. As to the absence of cerebro-spinal menin-

* Malt has also been used from time immemorial by the Japanese for various forms of dyspepsia and weak digestion.

gitis, in an epidemic form at least, there appears to be no question. Still more is this country to be congratulated on its escape from the ravages of diphtheria, that terrible scourge of the West. Though sporadic cases are not uncommon, I have never seen it epidemic. Indeed, in one instance only, have I seen it attack several members of the same family, including adults. According to my observations, most cases which terminate do so by the extension of the disease to the larynx, in other words, as diphtheritic croup. Simple membranous croup is common, and, as elsewhere, nearly always fatal. I have never seen a sufficient number of cases in one locality, however, with clearly traceable evidence of direct infection, to warrant its being called epidemic. An interesting question here suggests itself, as to the cause of this comparative immunity from two of the most fatal diseases of western countries. Measles, though occurring in an epidemic form, appears to do so only at long intervals, then completely dies out. The last epidemic was in 1861, twenty-seven years having elapsed between it and the previous one. It then swept from one end of the empire to the other in a few weeks, and, as we had an opportunity of observing, attacked all under twenty-seven years of age, or at a rough estimate 15,000,000 ont of the entire population, calculated at about 35,000,000.

The mortality was very great, it being estimated that in Yedo alone (then with a population of 1,500,000) the number of deaths from the disease was 75,000.

Some years ago we published in the *Pacific Medical Journal* a chronological record of wide-spread epidemics of the disease in this country, dating as far back as 552 A.D. Since that time there have been thirty-seven epidemics, the longest interval being one hundred and fifty-two years, and the shortest eleven. That the disease dies out, and requires a fresh importation each time of its appearance, seems borne out by the fact that since the epidemic of 1861 I have not seen a single well-marked case of measles among the natives, nor have I heard of its existence elsewhere. Rubeola Germanica is quite common, however, and is not unfrequently mildly epidemic. Hooping, or the hundred day cough, as it is termed by the natives, and mumps, present nothing unusual in their type and degree of prevalence from what is observed of them in the West.

Small-pox, till vaccination was introduced by Dr. Merrick in 1849, was exceedingly prevalent, both in its endemic and epidemic forms. Since that time, its visitations appear to be somewhat less frequent. It was not till the severe epidemic of 1875 swept over the country, however, that I succeeded, as sanitary advisor to the Government, in getting systematic sanitary measures adopted for its control and future prevention. During the epidemic, a house to house inspection was instituted, and all attacked with the disease were removed to the hospital, or visited at their homes by a corps of physicians, detailed for this especial duty. All persons who had not been protected by a previous attack of small-pox, or been vaccinated, were ordered to present themselves to the vaccinating bureau for the operation. The registration of the entire population, being a part of the municipal organization of the Government, a list of the members of each household was furnished the vaccination bureau, and their names checked off as they presented themselves, so that few were able to evade the law.

Though five years have now elapsed since this system was inaugurated in this place, there has been no return of the disease even in an endemic form.

Typhus fever, though common, is not so prevalent as generally supposed, from the fact that nearly all continued fevers, including malarial intermittents, are reported by the native doctors as typhoid.

Dysentery, even as a sporadic disease, is rarely met with in this section of the country, though reported as occasionally epidemic elsewhere. Asiatic cholera has been epidemic in Japan several times, and twice within twenty years, viz., in 1861–1862, and in 1877, 1878, 1879.

No reliable information exists of the mortality of the epidemics of 1861–1862, though it is known to have been very great. The number of cases in 1877 were 12,378—deaths, 6,508, or 54.56 per cent.; in 1878, cases, 975—deaths, 532, or 54.56 per cent.; in 1879, cases, 164,264—deaths, 97,422, or 59.30 per cent. This year (1880) a few cases have been reported, but we doubt if any of them were real Asiatic cholera.* Marsh malarial affections are very prevalent, and complicate almost every form of disease. Common ague, however, in which the three stages are well marked, is rare in this section of the country, and I have seen but few cases of any other than quartian type. The marked form of the disease is by far the most common, and, in fact, comprises ninety per cent. of all the cases met with. Congestive and pernicious malaria, though occasionally observed, are not common.

Beriberi, a disease *having its origin in a specific soil echalation*,† is very common in this country. Its areas of especial prevalence are the low-lying towns on the eastern and southern shores of the islands collectively forming this empire. Consumption is very common, and furnishes, as elsewhere, a larger percentage of deaths in adults than any other disease. Scrofula is, according to my observations, somewhat rare. Leprosy, though indigenous to Japan, and met with in almost every part of the country, is evidently kept in check by the belief of the people in its hereditary nature, and as a consequence a careful inquiry by the families of both parties about to marry into each other's history, with special reference to the existence in them of this malady.

Syphilis is very prevalent, so much so that we think we are safe in saying that three-fourths of the adult male population, especially in the large towns, suffer from it sooner or later. Our observations have led us to the opinion, however, that its manifestations are less severe than among Europeans. Thus, with the immense opportunity which we have had of seeing the disease, we have found the secondary lesions, as affecting the mucous membranes, in most cases very transient, and often wanting caries of the bones and other tertiary manifestations. We also regard as relatively infrequent the protecting influence of ancestral saturation with syphilitic poison, which may possibly explain this mild type of the disease in this country. The fact that, in former times at least, every case of primary syphilis was treated by thorough mercurialization, may account for the mildness of the tertiary lesions mentioned. In support of the former hypothesis we have the well known historical fact that the English soldiers, during the Peninsular wars, suffered much more severely from syphilis than the people of the country from whom it was contracted. We may mention in this connection that it is a popular opinion in Japan that small-pox is much more severe in its natural form in

* See my Report on Cholera Epidemics in Japan.

† See my Thesis on Beriberi, or the Kakké of Japan, in the Imperial Chinese Customs Report for 1880.

those whose parents had never had the disease, or who had been prevented from having it by vaccination. Even if our observations as to the mild type of syphilis in Japan be correct, it is impossible to believe that its effect on the whole people is not profound, and serves to explain in some degree the generally admitted fact of the physical inferiority of the race as compared with Europeans, and also the relative slow increase of the population thus favorably situated during the last two hundred years.

The Government have established lock hospitals in many of the larger towns, where weekly examination of all licensed prostitutes are made, and those diseased kept under surveillance. The effect on the prevalence of syphilis is not definitely known.

CAUSE OF DIPHTHERIA

In the Family of Samuel Crump, Esq., Montclair, N. J.

By J. W. PINKHAM, M.D.,

MONTCLAIR, N. J.

Although I saw but little of the cases referred to below, having had under my care only the fourth child after the third day of his attack, I have had an opportunity to collect some instructive facts connected with the matter, which I think will be of general interest.

Diphtheria in Montclair has been a thing of rare occurrence, only thirteen fatal cases having been recorded in the last fourteen years.

At the time the disease showed itself in Mr. Crump's family there were no other cases in town, and I believe there have been no cases since.

Mr. Crump's residence is situated on a hill-side, about three hundred feet above the sea level. The ground is dry and slopes toward the east. The house is exposed on all sides to the direct rays of the sun. The cellar is dry.

The plumbing in the house is confined to the kitchen, the laundry, the bath-room, and one bedroom on the second floor. Every waste-pipe is trapped and every trap is ventilated. The soil-pipe extends above the roof, and is supplied with foot ventilation. The cesspool is thoroughly ventilated. Nearly every room in the house is supplied with a separate ventilating shaft. In the opinion of experts the house could not have been unhealthy from sewer-gas nor from soil dampness.

The house is warmed by a hot-air furnace, called the Gould Hygienic Furnace, the peculiarity of which is that it presents a large radiating surface and thus does not overheat the air. Mr. Crump, in order still further to ensure himself against the evils of overheated air, caused his furnace (*i.e.*, the radiating surface) to be covered with a coating of clay; and, to prevent the air from becoming too dry, a large evaporating dish was placed in the hot-air chamber.

The household consisted of thirteen members, seven adults and six children. The adults were Mr. and Mrs. C., two lady relatives, and three servants. The children were all under eleven years of age. The family was an unusually healthy one, and no member of it, so far as can be ascertained, had been exposed in any way to the contagion of diphtheria. There had been no case of the disease in the vicinity of Mr. Crump's house for many years, so far as known. Twenty-seven feet from the cold-air box which supplies the above-mentioned furnace with air, is the fence which separates Mr. Crump's lot from the adjoining premises. This cold-air box was, previous to the attack, on a level with the ground, and presented in transverse section an area of two square feet.

On the eighth day of December, 1880, there were spread on the grounds of the above-named adjoining premises the contents of a cemented pit, which, during the summer, had received the waste from the stable and the kitchen. At the time it was spread, it was noticed that the odor was very bad, and it was particularly noticed by those who passed along the carriage-way between Mr. Crump's house and the place on which the refuse was spread.

Now, keeping in mind the relative position of the two places, viz.: that Mr. Crump's lies to the east and is somewhat lower, let us glance at the following table taken from the carefully kept meteorological record of William A. Whitehead, Esq., of Newark:

Dec., 1880	Temperature.			Wind.	State of Weather.
	Min.	Max.	Mean.		
8	14	27	20	N. N. W.	
9	11	12	11+	W.	
10	6	23	15	N.W.	
11	6	23	15	N. to W.	
12	19	37	28	W.N.W.	
13	32	39	35	W.S.W.	Cloudy.
14	30	40	35	W.	Fair.
15	32	39	35	W.S.W.	Clouds and rain.
16	32	38	35	W.S.W.	Clouds and rain.
17	21	30	25	N.W.	Fair.
18	23	32	27	W.N.W.	Fair.
19	19	33	26	N.N.W.	Fair.
20	23	31	27	N.	Cloudy.
21	27	32	30	N.E.	

It will be seen that the thermometer remained below the freezing point until the 13th, when it reached 39°. On this day it was cloudy and the wind was westerly. On the 14th the temperature was 40°+, with the wind directly west. On the 15th it was 39°+, wind westerly, with clouds and rain. On the 16th it was 38°+, wind westerly, with clouds and rain.

Thus, for nearly five days the temperature was considerably above freezing nearly all the time, the wind was constantly from a westerly direction, and during the two days when the temperature was highest there were clouds and rain. During these warm, moist days the odor from the refuse described above was very marked, and as its source was only twenty-seven feet from the entrance to Mr. Crump's cold-air supply-box, and as the wind was constantly in the direction toward Mr. Crump's house, the gases which made themselves so perceptible in the neighborhood must have been drawn into the furnace with the inflowing air, and must have been distributed to that part of the house heated by the furnace.

Mr. and Mrs. Crump and the children slept in bedrooms warmed by this heated air from the furnace.

The remaining five members of the family occupied bedrooms which were not so warmed. On the 22d of December, one of the children, aged six years, after two or three days' illness, presented unmistakable evidences of diphtheria, and died on the 26th. A second child was attacked on the 26th, a third child and Mrs. Crump on the 27th, and a fourth child on the 29th. The second and third child died on the 31st of December and the 1st of January respectively. Mrs. Crump and the fourth child recovered. In the course of seven days, of the eight persons who slept in the furnace-warmed rooms, five were attacked with diphtheria, three cases terminating fatally. The remaining members of the household, five in number, who occupied rooms not supplied with registers, all escaped.

It is worthy of notice that, of all the attendants, physicians, nurses, and friends, who were brought into close relation with the sick day and night for more than ten days, with possibly one exception, not a person contracted the disease.

The exception referred to was that of a colored nurse, the brevity of whose attack (two or three days) makes it fairly questionable whether it was diphtheria she had, or some affection which simulates it. Now, when we consider the immunity of so many people, for so long a time, and so fully exposed to the disease in so malignant a form, does it seem probable that one of these children should have contracted it from a person so slightly affected as to be unconscious of illness, or should have come in contact with the poison in a place where the disease did not exist, and have transmitted it in so short a time to so many members of the family?

On the other hand, when we consider the close proximity to the large cold-air box of a mass of putrefying animal and vegetable matter, the effluvia from which were, for five days, constantly mingled with the air which, in a continual stream, passed through the hot-air chamber of a furnace which heated it, we may fairly suppose, to a degree not too great to do otherwise than render more active the already poisonous gases with which it was loaded, when we take into account the large evaporating dish contained in this hot-air chamber, which supplied an abundance of moisture, and the still more important fact that, of those most exposed to this air from the furnace, five out of eight were seized with diphtheria in the space of one week, while the five who were least exposed all escaped, does it not seem probable, whatever views we may entertain concerning bacteria and specific germs, that we have in these poisonous effluvia the essential cause of the disease in this particular instance.

ANTISEPTIC LIGATURE OF RIGHT AND LEFT FEMORAL ARTERIES IN THE SAME SUBJECT, FOR DOUBLE POPLITEAL ANEURISM,

With Successful Result in both Instances.

By CHAS. K. BRIDDON, M.D.,

Surgeon to the Presbyterian Hospital, New York.

(A Paper read before the New York Surgical Society.)

For the histories of this case I am indebted to Dr. John F. Duffield, assistant surgeon to the hospital. George Rassmussen, aged thirty-two years, native of Denmark; married; sailor; admitted to Presbyterian Hospital July 15, 1879.

Family history.—Is uncertain as to whether his parents are living, but none of the other members of his family have been the subjects of disease such as that from which he suffers.

Previous history.—Has enjoyed very good health; had intermittent fever seventeen years ago, gonorrhœa three years ago, and contracted constitutional syphilis eight years ago.

Present illness.—Three weeks since patient noticed that the right knee became somewhat stiff, and that he could not move it as readily as the other; he kept on working, however, seeking relief from such domestic remedies as were suggested to him by his friends; pain of a dull, but sometimes shooting character supervened, and soon began to interfere with his rest at night, when he called in his family physician, who detected a swelling in the popliteal space and pronounced it aneurism.

On admission, presents a tumor in the right popliteal space about the size of a small lemon, deeply seated on the outer side of the inner hamstring; it conveys lateral pulsation to the hands placed on either side, which is synchronous with the heart, and which ceases on compressing the artery above; no bruit can be detected.

A series of successes in the treatment of aneurism by catgut ligature and the Lister dressing led the surgeon in charge (Dr. Briddon) to adopt this mode, without any preparatory compression or flexion.

July 17th.—The operation was made in the usual position in Scarpa's space, at the point where it is under cover of the sartorius; a catgut ligature (superfine violin string, E. No. 70) was used; of course the whole operation was conducted under a reliable spray, and the wound was dressed with all the antiseptic precautions; the leg was encased in a thick layer of cotton-wool which was maintained in position by a loosely applied muslin bandage.

July 29th.—Nothing of moment has occurred up to this date; there has been a very slight pulsation discernible in the tumor, but only such as is regarded as favorable to the more enduring processes of cure. There has been a slight show of discharge beneath the margin of the dressing, and it is changed under the spray; the incision was found nearly united by first intention.

August 1st.—Dressing removed, wound healed, tumor very much diminished and without pulsation.

August 13th.—Discharged cured.

Three months after leaving the hospital the patient presented himself at the office of Dr. Briddon, with a tumor in the left popliteal space. A week before some stiffness in the joint directed his attention to the part and he discovered a swelling about the size of a hen's egg. It pulsated, and the pulsations were synchronous with the heart, and were stopped by compression of the artery. Being anxious to make some provision for his family preparatory to entering the hospital, delay was considered justifiable, though his occupation as a longshoreman exposed him to some risk; and recognizing the lesion as due to the degeneration depending upon syphilitic sudarteritis, he was advised to be careful, to take increasing doses of iodide of potassium, and to present himself occasionally for observation. He took the iodide until the dose reached ninety grains a day, and this dose was continued for many months. At first there was an unmistakable diminution in size, and then the tumor remained stationary. In the month of August, during the absence of Dr. Briddon, he strained his limb, throwing it into the position of hyperextension. This was followed by pain and rapid increase in size of the swelling. He was confined to his bed and attended by his family physician, who prescribed such means as were likely to relieve his severe pain. He was seen by Dr. Briddon on the 9th of September, and was sent to hospital for immediate operation. The tumor was very large, filling the entire space, bulging the hamstrings on either side; there was some effusion into the cavity of the joint. The leg was considerably swollen, and he had not slept for many nights.

No remains of the aneurismal swelling could be discovered in the right space.

Careful measurements of each leg were taken at this time, as follows: left leg, eighteen inches in circumference over the patella, and seventeen inches in circumference three inches above the patella;

right leg, thirteen and three-quarter inches in circumference over the patella and thirteen and a half inches in circumference three inches above the patella.

September 13th.—An operation precisely similar to the one on the other leg was performed. The superfine violin string, E, No. 70, was employed in securing the artery as before; strict Lister precautions were observed throughout; the wound was dressed with the usual dressings, and the entire limb enveloped in cotton batting, secured by a loosely applied roller-bandage. Immediately after the ligature was applied measurement of the left knee showed its circumference to be, over the patella, seventeen inches, and three inches above the patella sixteen and a half inches.

September 14th.—A.M.: temperature, 99¾° F.; pulse, 92; P.M.: temperature, 102° F.; pulse, 104. No pulsation was discernible in the sac; no pain.

September 18th.—Temperature normal; pulse, 76. The highest temperature since last date was 93¾° F., on the evening of the second day after the operation. No pulsation has returned in the sac; no discharge has appeared through the dressings; no pain. Complains merely of the limb feeling "heavy."

September 25th.—Cotton removed from the sac. No pulsation or *bruit* whatever was obtained on the most careful examination. The tumor was markedly diminished in size, and its outlines could readily be mapped out.

October 1st.—The dressings, which had not been changed since the operation, were removed to-day, and the wound was found to have healed throughout by first intention. The cotton has been gradually removed from the entire leg. Rather less numbness; specific treatment renewed; ordered unguentum hydrarg. to be rubbed in the axilla every night; general condition excellent.

October 10th.—Measurement of left knee over the patella, sixteen and three-quarter inches; three inches above the patella, fifteen and a quarter inches; three inches below the patella, fifteen and a half inches. Says the left foot feels numb, though he feels the point of a pin when applied to any part of the foot.

October 12th.—The foot does not feel numb, and there is no pain in the knee; no recurrent pulsation has occurred; general condition good; appetite good; bowels regular.

November 7th.—Discharged, with swelling much diminished in size, and pulseless.

THE NEW BRIGHTON CODE OF SANITARY ORDINANCES.—We notice that in the very elaborate code of sanitary ordinances recently put in force at New Brighton, S. I., the following order is found: "Every householder or head of a family, in a house where any case of infectious disease may arise, shall report the same to the Board of Health within twelve (12) hours from the time of his or her first knowledge of the nature of such disease, under a penalty of ten dollars ($10) for omission so to do." By this order the responsibility of notifying the authorities is put upon the householder, not the physician. We have always contended that the state had no right to impose this responsibility on the physician without remuneration, and whether he wishes it or not. We shall watch with interest the working of these new sanitary ordinances. If they can be made practicable the very efficient President of the Health Board, Dr. Carroll, will surely make them so.

Reports of Hospitals.

PHILADELPHIA HOSPITAL, PHILADELPHIA.

SERVICE OF DR. EDWARD T. BRUEN,

ATTENDING PHYSICIAN.

THE SYMPTOMATOLOGY OF ACUTE MILIARY TUBERCULOSIS CONSIDERED IN REFERENCE TO THE DIAGNOSIS—A WARD CLASS DEMONSTRATION.

THE case you will analyze with me this morning is very typical of its kind, although its symptomatology, studied in detail, presents but a very few cardinal features. The disease is rare in the present form, but the observations I shall make to you are dictated by a study of nine cases of similar disease in which the diagnosis has been confirmed by autopsy. These cases all occurred in the wards of this hospital during the past eight years.

As we contemplate the case we notice that the respirations are quickened, that there is a dry, hard cough, attended by but little expectoration, and the complaint of our patient, a German, is that he has discomfort referred to the chest; thus our attention is directed to the examination of both the heart and lungs at the outset. When you examine the lungs you will find that the physical signs negative the presumption that any of the ordinary diseases of these organs are present. Yet you will be able to combine these vague physical signs so that you may erect them into a typical mental picture alone indicating the disease I shall endeavor to prove to you is present, viz., acute miliary tuberculosis. If on a journey two roads terminate at the same point, the traveller will usually prefer the shortest and most direct. In medical diagnosis it is well to seek to isolate the prominent features of a case, and thus often a rapid and sure diagnosis will reward you.

The patient, L. S——, says that for six weeks past he has had fever, sweating at intervals, dry cough, dyspnœa, and rapid breathing. He has been confined to bed and felt ill. The cough has not been attended by expectoration or hemorrhage; for the past week the sweating has increased; sometimes he has been drenched with moisture, and this has happened both in the daytime and at night.

As the salient features you will notice that the pulse is very rapid—144 per minute—and this rapid beat has been a sustained feature during the past week, the date of the patient's admission; it has been taken three times daily, and never has been found below 130. This persistently rapid pulse is a fundamental symptom of this malady, and is most unvaryingly present. Many writers allude to it, but the diagnostic prominence I assign to it has not been enforced; the pulse is also small, often it is thready.

Tubercle is described by Charcot as distributed in the tubular structures of the body—in the lungs. We find it in the sheaths of the arterioles, the sheath of the bronchial filaments, and in the lymphatic vessels. The lumen of the arterioles is diminished, the aëration of the blood is less perfect; hence, perhaps, the rapidity of the cardiac action for the left ventricle is illy supplied with blood. But we also, from this explanation, can understand a second symptom, viz., the dusky hue of the face, which at times is flushed, as in typhoid pneumonia, at times is quite pale; if this patient change his position the flush is seen to go and

come. The general surface of the body in the latter stages of these cases is also dusky, and often the appearance of the patient will forcibly remind one of the cadaver after death from a blood disease. Perhaps the interference with the circulation above mentioned may serve to explain this appearance of the body. The sweating and condition of the skin have always reminded me of the sweating of the death agony, and possibly a similar physiological explanation will serve us. The scanty sputa is readily understood when we reflect that the amount of catarrh of the bronchial tubes produced by the infiltration of miliary tubercle is slight. Now, we readily discover that no valvular heart disease exists. In a moment we shall demonstrate that pneumonia does not exist, even if the length of the sickness had not practically excluded acute inflammation of the lungs, for the patient says he has been sick seven weeks, and I ask you, Does not the individuality of the disease loom up? Now for the physical signs. All over the chest, on both sides, a vesiculo-tympanitic resonance is heard, though in one or two patches, the size of a silver dollar, posteriorly, slight dulness can be developed. Auscultation suggests an exaggerated inspiratory murmur, with feeble expiration, of the type heard in emphysema, or in supplemental action of a healthy lung when its fellow is disabled; nowhere is the breathing bronchial. With this you can hear, on inspiration alone, numerous fine, slightly moist râles. These are similar to the râles of pneumonia, but in this case they are heard at both apex and base of both lungs. They are somewhat like the fine râles of capillary bronchitis, but who of you has seen a case of this disease without some expectoration; and then this disease is apt to be associated with the chest and heart alterations of emphysema or the pre-existence of Bright's disease, and the temperature range is not similar. We also hear some dry sibilant and sonorous râles.

Recurring to the pathology of the disease, we can understand the development of râles as just described from irritation of the bronchial mucous membrane, and the catarrhal exudation in the finer tubes. There are also some dry pleural frictions, and a restricted movement of the right lung as compared with the left, indicating a tubercular pleurisy with plastic exudation, but yet both lungs expand and retract during breathing. In reflecting on the characteristics of the respiratory murmur, remember the vesicles of the lungs are truly hyperdistended with air as in emphysema. The respiratory act is imperfect because of the obstruction to the exit of air due to the catarrhal secretion in the finer bronchial tubes. You notice that the physical signs cannot indicate consolidation in any of its forms, and the *tout ensemble* of the case does not indicate the ordinary forms of bronchitis. Let such physical signs be appropriate to acute miliary tubercle when combined with the previously enumerated general symptoms.

The temperature is of value, but chiefly from a standpoint of prognosis. The range is from 100° F. to 103½° F. during the disease. The higher temperatures given by Wunderlich have a different significance, as I shall explain in a moment. In the week before death (for this disease is fatal) the temperature may fall to 97° F., to rise in the evening to 101° F.; but daily in that week it will be found below 99°. I regard this as very constant. The higher temperatures given by Wunderlich and Niemeyer I think may be understood to refer to acute miliary tubercle complicating advanced inflammatory phthisis, in which case, besides the older cheesy material, life may be prolonged till cheesy metamorphosis of the tubercle has occurred; whereas in the acute primary tuberculosis death occurs before much or any cheesy degeneration occurs. In other respects the symptomatology is essentially the same, save that in the primary disease there is no emaciation or evidence of the wasting of consumption always present in the secondary form; and in cases of general tuberculosis complicating consumption the physical signs of phthisis are present.

The duration of acute miliary tuberculosis is from seven to nine weeks, usually the shorter period. Let me allude to some interesting facts relative to this disease, apart from the study of this case, as representative of its class. You will, by inspection of this case, discover that he has had suppurative inflammation of the glands of the neck at some prior period. Search, then, for enlarged glands, note if they have suppurated, and whether scrofulosis or consumption are hereditary in the family; for the connection between these conditions and this disease is very intimate, and it is essential that some focus of antecedent inflammation, usually in a cheesy state, be present to form a nucleus for absorption and the lighting up of tuberculosis on the smallest provocation. In the group of physical signs you can hear a metallic tinkling râle and distant cavernous breathing at the right apex. I believe these signs indicate a cavity deeply situated. The cavity must be very small, and is probably the result of some prior attack of catarrhal pneumonia.

It is common to exclude typhoid fever in a theoretical diagnosis. The contrast is seen in the rapid pulse early in the case without the typhoid state, the cyanosis, the physical signs in the lungs, the evident respiratory disturbance, the sweating, the absence of characteristic rise in temperature, and the absence of prodromes from the history.

The ensemble is more that of typhus, for in this disease there is an early rapid pulse, a dusky hue of skin, and in the cases of typhus which occurred in this hospital a year ago, the temperature was similar, never very high. The history of the case, a minute analysis of the pulmonary symptoms, the typhus eye, the environment* from which the case developed, are, perhaps, the safest indications for diagnosis by exclusion, while the eruption, if it be characteristically present in typhus, is conclusive. It is only, of course, in large seaboard cities where this disease can be a source of confusion.

We met five days ago, and yesterday one patient died, as I foretold by consultation of the temperature chart. The entire tissue of both lungs can be seen studded with the most perfect translucent granulations, alone characteristic of miliary tubercle. Nowhere is the tissue of the lungs consolidated; on the contrary, they bulge with air, and yet they do not collapse, showing the tissue is more condensed than natural, and the lung feels as though infiltrated with fine particles of shot. In the right apex you will find a small cavity, the size of a small egg of a pullet, but the amount of retraction of the adjacent lung, and the proliferation of connective tissue in the neighborhood of the vomicæ, all show that cicatrization had progressed considerably, and justifies my previously expressed opinion that it would prove the result of some prior catarrhal pneumonia, possibly a

* The cases received into the Philadelphia Hospital during last winter, and so far in this season as well, have originated in widely distant sections of the city—so sporadic has been its development that environment has been of little value as a diagnostic aid, although the cases have originated among the poor.

year, possibly longer, before the last sickness. The entire pleura of the right side is adherent from antecedent pleurisies, and you can see the miliary tubercle from the present attack. The bronchial glands are much enlarged, and likewise the mesenteric. In both liver and spleen you will see tubercles, but none exist in the intestines or kidneys. In these cases the intestines often escape, and, even if involved, death happens before much, if any, ulceration occurs; so diarrhœa is not a symptom, excepting, indeed, in cases in which acute miliary tuberculosis terminates in phthisis, when follicular catarrh or ulceration of the bowel is frequently found. The membranes of the brain also enjoy an immunity in the adult quite the reverse of the history of similar cases of tuberculosis in the child.

In leaving the case, let me express the hope that if you approach the symptomatology of your cases of this malady as I have indicated, you will find the diagnosis comparatively easy.

Progress of Medical Science.

The Bloodless Method of Performing Surgical Operations.—Prof. Esmarch, of Kiel, again alluded to this subject at the Congress of German Surgeons in Berlin. (Reprint from *Langenbeck's Archiv*, vol. xxv.) He remarked that seven years had now elapsed since he had first advocated the use of the bloodless method for surgical procedures. Since then most surgeons had given his method a trial. Many eminent and experienced physicians had, however, abandoned it, on account of the secondary hemorrhage following the removal of the constricting bandage. This was to be regretted, for none could deny the great advantages to be gained by artificial ischæmia. Esmarch attributed to a defective *technique* the disadvantages claimed to be associated with his method. Nor did he think that the modifications variously suggested were calculated to obviate failures from this source. He had himself been occupied with further improvements, and had been so far successful that he performed most of his recent operations on the extremities with absolutely no loss of blood.

The present mode of procedure in the three principal varieties of operations on the limbs, *i.e.*, amputations, excisions, and sequestrotomies, was then described. In amputations all the visible vessels were carefully tied, but the constricting tube was not at once removed. The edges of the wound were then united by deep catgut sutures, after which a short drainage-tube, capable of absorption, was fixed at the most dependent portion of the wound; finally, a compressing retentive dressing (*comprimirender Dauer verband*) was applied, and then the constricting tube was removed, the limb being maintained in a vertical position. The patient, having been placed in bed, his stump was kept in the vertical position for half an hour longer, after which time it was placed horizontally. He had performed twelve amputations in this way, and in no instance was consecutive hemorrhage observed. The dressings remained in situ for two weeks. At the end of this time they were removed, and a narrow streak of dried blood was all that was found to correspond to the cicatrix.

In exsections he had formerly applied the dressing before removal of the constricting tube, but he had afterward abandoned this plan, owing to the occurrence of secondary hemorrhages in consequence of incomplete compression. Recently, however, he had again adopted this former method, because now he had improved the method of dressing. At present he secured the visible vessels after the operation, and proceeded in essentially the same manner as in amputations, the limb being secured to a suitable splint in the vertical position, and so held for about half an hour, after which time the patient was allowed to place it in a more comfortable position.

In this way, since 1878, he had performed fifty-six exsections, and in no case had secondary hemorrhage taken place. In thirty-three cases the dressings were left undisturbed for from three to four weeks.

As regarded sequestrotomies, he had abandoned his former method of plugging the osseous cavities with carbolized cotton, etc. At present his method was as follows: The bone cavity was thoroughly cleansed with solutions of carbolic acid and chloride of zinc, the edges of the wound were then united by deep catgut sutures, drainage-tubes capable of absorption inserted, and the constricting tube removed after completion of the retentive dressing. He had employed this method successfully in twelve cases, and in no instance had secondary hemorrhage necessitated an early renewal of the first dressing. Similar dressings were applied in a precisely similar manner, in such operations as the extirpation of tumors of the limbs, nerve-stretchings, etc. The results in all cases were very satisfactory, which he attributed to the absence of all hemorrhage, either primary or secondary.

Cannabis Indica in Migraine.—Dr. Lothrop, in a paper read before the Buffalo Medical Club, advocates anew the exhibition of this drug in persistent hemicrania. (*The Buffalo Medical and Surgical Reporter*, December, 1880.) After a short review of the subject, in which reference is made to an excellent article by Dr. Seguin (Medical Record, vol. xii., p. 774, 1877), the writer explains the principle of treatment as laid down by Greene. This was "to maintain, by the use of small doses of the agent, a constant influence upon the nervous system for a long time, the same as is required in epilepsy by the use of the bromides." It is stated as a matter of course, that at first no appreciable effect is observed, and that not until the use of the remedy is persevered in for many weeks, and the nervous system kept under its influence for a considerable time, will the patient find an appreciable diminution in the severity and frequency of the attacks. It is well to commence with one-fourth grain of the extract before each meal, for the first fortnight. The dose may be increased to the third of a grain for the second fortnight, to be augmented to a half grain at the end of four weeks. This amount will generally be sufficient, and should be continued for several months. Success here is only attained by persevering effort. A severe case of hemicrania, in which hereditary influences bore a prominent part, is described by Lothrop in support of these views on the efficacy of the prolonged use of cannabis indica.

Hydatid Cyst of Right Kidney—Treatment by Puncture and Injection of Tincture of Iodine.—Dr. Weinlechner, of Vienna, reports the following case (*Ber. d. Krankenanst. Rudolphstiftung in Wien vom Jahr.*, 1879): J. O., aged eighteen, was admitted to the hospital with an abdominal tumor, situated in the right side, and being about the size of a child's head. The tumor had been previously

painful, but showed no distinct tenderness on admission. Some fluid contents were withdrawn by exploratory puncture, but a definite diagnosis could not be made at that time. Later a large amount of fluid was removed by aspiration, and the cystic cavity immediately injected with two ounces of a solution containing equal parts of tincture of iodine and water, with the addition of a small quantity of iodide of potassium. The injected fluid was allowed to remain in the cavity. Subsequent examination of the fluid removed by aspiration, revealed the presence of the characteristic hooklets and scolices of the *echinococcus hominis*, or common hydatid. The seat of the sac was in the right kidney. No untoward symptoms followed the injection, and the tumor gradually diminished in size, until at length it could no longer be felt. Several months afterward the patient died from septicæmia, following exsection of the knee-joint. At the autopsy the remnants of the sac were found adhering to the lower extremity of the right kidney, and involving a small portion of its tissue. It still contained some collapsed hydatids and a small amount of yellowish fluid. Dr. Weinlechner observes that but for the untimely death of the patient, complete shrinkage of the sac would undoubtedly have taken place.

Excision at the Hip-Joint for Acute Infectious Osteomyelitis.—A recently published thesis by Driessen presents the personal views and experiences of Volkmann on the above subject. Two forms of this affection are recognized: 1, those which appear early, and, 2, those of later appearance. Under the first heading two varieties are described: First, those with but slight serous articular effusion, due to the irritation of the encroaching osteomyelitic process as it nears the joint. Such forms have a mild type, and spontaneous recovery is the rule. Secondly, those of a malignant character and diffuse ichorous inflammation, where the epiphysis is speedily involved in the destructive articular process. This variety is of frequent occurrence at the hip, and the course of the disease is commonly of such rapidity that an early death from septicæmia, as a rule, precludes the possibility of excision.

As regards the second form of osteomyelitis, that of later occurrence, several varieties may be distinguished. First, there are the chronic obliterating affections, without marked symptoms, which frequently result in cartilaginous, and, finally, bony anchylosis. Then there are the sero-purulent affections, which take a subacute or chronic course. They are produced in consequence of the extension of the osteomyelitic process beyond the line of insertion of the articular cartilage. As a rule, the cartilage is not destroyed, and the whole course of the disease is comparatively mild. Articular mobility may be preserved. The last variety belongs to a severer type, and takes a subacute or chronic course. Ulcerative destruction of the articular cartilage is the rule. Caries is frequently found. In these forms exsection is generally a necessary operative interference.

Suppurative osteomyelitic diseases of other joints may be amenable to different forms of treatment, but in the hip-joint the acuity of the whole process and the profuseness of the products of degeneration, together with the deep seat of the joint, generally justify, or even necessitate, excision. In fact, the operation frequently becomes a vital indication.

The immediate object of resection is to freely open the joint so as to preclude the possibility of purulent accumulations, and permit irrigation of the surrounding abscesses as well as the joint itself. Excision, of course, also does away with the deleterious effects sure to follow the pressure of the articular surfaces against each other. In case the incision has been carried through necrosed bone, the latter should be allowed to remain until a sequestrum has formed. Any diseased osseous marrow should, however, be removed by the scoop.

Cases running an extremely rapid course, with speedy destruction of the hip-joint, are seldom seen in hospitals. But after the first stage of infectious osteomyelitis has passed, or in cases of slow development, the patients, as a rule, recover after excision; at least this has been the experience of Volkmann's clinic. Recoveries were observed in cases of apparently unfavorable prognosis—the patients having high fever, being extremely emaciated, showing considerable anasarca, and containing in their urine a large proportion of albumen.—*Centralbl. f. Chirurgie*, October 16, 1880.

Aural Symptoms in Bright's Disease.—Continuous or intermittent deafness has been described as a comparatively frequent concomitant of chronic nephritis by Rosenstein and Rayer. More recently Dieulafoy has called attention to such aural complications. Pain in the ears and tinnitus aurium have been added to the list of significant precursors of uræmia by these authors. A separate thesis was lately published by Pissot, entitled *Les troubles auditifs dans le mal de Bright*. Hitherto, however, the nature of aural complications in Bright's disease has been regarded rather in the light of functional disturbance than anatomical lesion.

Dr. Gurovitsch, of Odessa, records a case of parenchymatous nephritis where aural disease became a prominent complication, and where definite lesions were found. The case was that of a soldier, aged twenty-two, who had been a chronic sufferer from malarial affections. On his admission to hospital he had an intermittent fever of an irregular type. He complained of pain in the right ear, and partial deafness. It was ascertained that he had parenchymatous nephritis. Soon a purulent otitis media was developed, and later the previously healthy left ear likewise became implicated. Facial œdema was superadded to the other symptoms, and this became more marked with the increased violence of the aural symptoms. When the latter showed an amelioration, the œdema also partially subsided. Gurovitsch is at a loss how to account for this coincidence. The patient died of pericardial dropsy and cardiac failure, and at the autopsy the aural lesions were found to correspond to the diagnosis of otitis media purulenta.—*Berl. klin. Woch.*, October 18, 1880.

A Simple Method of Compressing the Brachial Artery.—Dr. Zenker, of Schivelbein (*Berliner klin. Wochenschr.*, October 18, 1880), describes a very simple method for effectually compressing the brachial artery, which may be readily practised by the unprofessional as well as the professional men. He claims neither priority of invention nor even originality of procedure, stating merely that the method is not mentioned in the customary text-books.

In giving the method a name he has chosen the designation of costal compression, or, as he states more correctly, "humero-costal compression." As indicated by this name, the method consists in pressing the arm against the thorax, thus effecting the compression of the artery between the ribs and the humerus. This may be done in two ways, either by

pressing the arm against the body, the latter being held in fixation, or, *vice versa*, by the pressure of the body against the immobilized arm, *e.g.*, lateral decubitus, with the arm pushed under the trunk.

As regards the actual performance of the simple manipulation the following hints are given: The person may stand or sit, and his body is to be pushed against some resisting article of furniture. The forearm is held in supination, flexed at right angles to the arm, and the latter then passed against the trunk in the axillary line, by placing the hand upon the region of the external condyle. It is surprising how little force is required to stop the pulse in the radial artery. The same result may be accomplished on one's own person, if the shoulder and arm are pressed against some unyielding surface, such as the wall of a room, and an effort made as if to lift or move it. The desired effect is also produced if the person is made to lie upon his arm. If, in addition, his head be placed upon the arm, the stoppage of circulation in the brachial artery will be complete. The position thus assumed by a patient or wounded person is called the brachio-lateral decubitus.

Successful Removal of an Ivory Exostosis from the Frontal Sinus.—Dr. Knapp has reported (*Archives of Ophthalmology* for December, 1880) an interesting case of an ivory exostosis situated in the frontal sinus, and its successful removal. A patient forty-eight years of age, healthy, and free from any constitutional taint, sought advice for a slight drooping of his right upper eyelid, which, however, caused him no inconvenience. The inner part of the lid was slightly prominent; conjunctiva and eyeball normal; mobility unimpeded; vision and ophthalmoscopic condition normal. The tumor was nearly as large as a flattened hazel-nut, slightly uneven, abruptly rising from the orbital wall and in unmovable connection with it. Its periphery had a hard bony feel, but the apex appeared somewhat yielding. In three months subsequent to the first examination the tumor had increased, and was no longer confined to the upper and inner corner of the orbit, but extended down a few millimetres below the ligamentum canthi internum. The operation consisted in making a curved incision from the middle of the superciliary arch along the lower margin of the brow, down to the insertion of the inner canthal ligament. Cutting in the centre of the incision at once down to the bony basis of the tumor, the stretched periosteum parted on being divided, and exhibited the yellowish-shining surface of the tumor; the uniform hardness of which along the whole line of incision, at once revealed the character of an ivory exostosis. The bony tumor had a slight constriction at its base and gave the impression of an exostosis united to the orbital wall by a broad basis of more or less cancellous tissue, such as is common in ivory exostosis of the orbit. After the osseous surroundings of the tumor had been removed, an examination with the finger revealed the fact that the upper half of the os planum and the whole anterior upper and inner half of the roof of the orbit were absent. The dilated frontal sinus and the opened nasal cavity were free from other growths. After the bleeding had ceased, the wound was united by silk sutures. When the patient came to he could move his eye freely in every direction, saw well with it, and had no diplopia. The tumor removed was completely free from periosteum, and consisted of compact bone throughout. The bulk of the tumor, about two-thirds, lay in the frontal and nasal cavities, and one-third projected into the orbit. No cicatrix was left, notwithstanding the fact that all modern antiseptic precautions were disregarded.

Charcot on Secondary Degenerations of Cerebral Origin.—From Charcot (*Cincinnati Lancet and Clinic*, November 13, 1880) we learn that in secondary degenerations of cerebral origin the nerve-fibres which compose the pyramidal fasciculi originate in the gray cortex of the Rolandic convolutions, and that from this point of departure they descend as far as the cord without forming other relations than those of contiguity with the different parts of the encephalon and the bulb which they traverse. In the case of descending degeneration, the nervous motor-cell should be considered as the structure which arrests, in the gray substance, the work of degeneration, and prevents its propagation to the nervous tubes of the anterior roots, which physiology unquestionably shows have mediate relations with the fibres of the pyramidal fasciculi. This hypothesis finds a support in certain pathological facts appertaining to the history of descending degenerations. The following case is cited: A woman was attacked with left hemiplegia, subsequent to a focal hemorrhage in the right hemisphere. The members of the paralyzed side, which were seized very early with contraction, began to diminish in size two months after the attack. The muscular atrophy was uniformly spread in all portions of the paralyzed members, and was accompanied with a notable diminution of electrical contractility. This muscular atrophy progressed very rapidly, the patient died, and at the autopsy it was seen, in sections of the spinal cord, that, besides the sclerosed fasciculus, there existed in the anterior horn of the corresponding side an alteration, of which the most salient points were their atrophy and even the complete disappearance of a certain number of the motor cells. Similar facts have been observed by Hallopeau while in the service of Vulpian, also by Leyden and Pitres. From these facts, then, we learn that the terminal extremities of the pyramidal fibres are in relation, in some manner, with the nerve-cells of the anterior cornua. As a rule, when there exists a secondary degeneration of the lateral cord, the cells resist, by reason of their autonomy, the invasion of the morbid process, and protect, so to speak, the corresponding anterior roots. But, in certain exceptional cases, and probably less rarely than is commonly supposed, under the influence of certain inexplicable conditions, the cells are attacked also, become atrophied, and consecutively the corresponding roots submit to a degenerative alteration. The final result of this invasion of the centrifugal nerves is the atrophy and degeneration of the muscles to which the diseased roots are related. In the case of Pitres the descending degeneration of the pyramidal fasciculus presented no anomaly in its disposition in the neighborhood of the altered cornua. No sign of a direct extension of the lateral fasciculus into the corresponding anterior horn could be found. That observation supports the idea that the propagation is not made by the intermediation of the connective tissue, but by following the course of the nervous fibres, which, parting from the pyramidal fasciculus, gain the horns of the anterior gray substance.

Auscultatory Percussion.—Dr. T. A. McBride has devised an instrument for auscultatory percussion of the abdominal viscera and the contents of the thoracic cavity, and in the *Archives of Medicine*,

for December, 1880, the results of his experiments on the cadaver are given. The application, however, was made only to the mensuration of the anterior surfaces of the heart and liver. The instrument consists of two solid pieces of hard rubber, connected with a rubber hinge. The pectoral extremities of this solid stethoscope are three millimetres square, and can be placed in the intercostal spaces without touching the tips, and can be brought sufficiently near the sternum without being carried in contact with the cartilages or bones. In proving this method with the modification in the stethoscope, the *modus operandi* was as follows: In marking out the anterior surface of the heart, the pectoral extremities of the binaural wooden stethoscope were placed over the fourth and fifth intercostal spaces, close to the left of the sternum, and percussion was made from the periphery to the præcordia by the auscultator, with closed eyes, by means of the percussion hammer, or index and middle finger of the right hand, indifferently. As soon as a change in the pitch and intensity of the percussion note was observed, the pitch becoming higher and the intensity increased, the spot where this change occurred was marked, and a sharpened knitting-needle ten inches long was thrust in at that point. This was done in each intercostal space of the præcordia, to the right and left of the sternum, and in the right mammary line, at points which were supposed to correspond to the upper and lower borders of the liver, and also in the mid-sternal line at the point supposed to indicate the lower border of the liver. Dr. McBride believes that by this method of auscultatory percussion with this new instrument, the busy general practitioner will be able, by the exercise of some caution and patience, to mark out the heart and liver, and most probably the spleen and kidneys, with a remarkable degree of accuracy.

Muriate of Pilocarpine a Specific for Diphtheria.—Dr. Guttmann, of Constadt (*Berlin. klin. Woch.*, October 4, 1880), claims to have found in the alkaloid of jaborandi a new and reliable specific for diphtheria. Divested of its enthusiastic personal coloring, his report is certainly deserving the attention of the profession; and this especially at a time when the ravages of diphtheria continue to claim its victims in untold numbers. Of course the positive assurances of a single observer as to the efficacy of a drug in combating a disease, which in many instances appears to us indomitable in its virulence, are always to be received with extreme caution. Moreover, our faith in the vaunted power of specifics has received many a rude shock since the nature of certain maladies has come to be better known, and the physiological action of drugs is more perfectly understood. On the other hand, there can be no possible harm in giving a wide publicity to the results claimed to have been obtained by the would-be discovery of new specifics; for the experience of the profession at large will speedily lead to a proper appreciation of curative effects, and the final verdict will then be either the corroboration of what was claimed or a quick consignment of the whole matter to merited oblivion. Thus it was with the antiphthisical benzoate of sodium—we had almost said "boom." Countless patients have obstinately refused to illustrate, by an amelioration of their pulmonary symptoms, that the benzoate was, indeed, the long sought for specific in consumption. And so it may be with the muriate of pilocarpine in diphtheria. Meanwhile, whatever its ultimate fate, we may at present briefly indicate the plan of treatment with which Guttmann claims to have obtained such invariably excellent results for the past fifteen months. He administers the drug in conjunction with pepsine, since the latter may, as he says, have a solvent effect upon the diphtheritic membranes. In adults half a grain to one grain of the muriate of pilocarpine is exhibited in an eight ounce mixture. In addition to this ingredient, the solution also contains half a drachm of pepsine, and a few drops of muriatic acid. Adult patients are directed to take the medicine hourly in tablespoonful doses. As a necessary adjuvant toward a proper action of the remedy, the use of strong wine (half an ounce at a time, after each dose of the medicine) is insisted upon. Children are required to take proportionately less, both of the drug and the wine.

In no case did Guttmann observe unpleasant symptoms following the use of the alkaloid. Its sialogogue action was always promptly manifested. With the establishment of copious expectoration the febrile movement diminshed in intensity, and the local symptoms rapidly improved. The patients are said to have been cured in from one to four days. He observed recoveries under this regimen of patients who, under ordinary plans of treatment, must have been considered as hopeless cases.

So much for the author. It will be seen that he claims a great deal. But even if the experience of others should confirm only a tithe of the invariably good results which he so rapidly obtained, the muriate of pilocarpine must still be added to the list of drugs which may be potent for good in the treatment of diphtheria. In conclusion, it may be remarked that a new observer, Lax (*Allgemeine med. Cent. Zeitung*, No. 87, 1880), has already come to the front with the corroborative testimony of ten severe cases rapidly cured by Guttmann's method. In three additional cases of Lax large masses of diphtheritic membranes were discharged, partly by expectoration and partly by the nasal passages. Time and experience will soon show whether this novel method is destined to gain the firm footing of permanent usefulness.

Epidemic Orchitis.—Dr. Heller reports the epidemic occurrence of orchitis in a garrison where mumps was at the time a frequent disease. Twenty-nine cases were observed, and of this number twenty-six showed the characteristic symptoms of epidemic orchitis. In only eight cases mumps was ascertained to have preceded affection of the testicles, and in two cases both diseases were simultaneously developed. The course of the disease was different from gonorrhœal and traumatic orchitis. Marked constitutional disturbances were seen in ten cases. Ten cases were re-examined some months afterward, and five of these showed atrophy of the testicles. In one patient the organ remained tender for a long time, and four years after, the primary affection was found to be reduced to half its normal size, and was even then more sensitive to the touch than the healthy testicle. —*Berl. klin. Woch.*, September 20, 1880.

The first number of a new review, the *Archives d'Ophthalmologie*, has just appeared in Paris. It is said that Professor Ball and Dr. Luys contemplate publishing a journal of mental and nervous disease. It will be entitled *L'Encephale*.

Dr. Garrigues' Report on Ovarian Cyst.—In the report on an ovarian cyst, Record, January 1, p. 19, line 15, read *myxoid* instead of *mixed*.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 22, 1881.

PROSPECTIVE MEDICAL LEGISLATION AT ALBANY.

THE medical profession in this state has already secured two of the most needed pieces of legislation: the establishment of a state board of health, and the regulation of the practice of medicine. It is not likely that anything of equal importance will come up during the present session of our legislature. Still there will be a number of questions introduced of more or less interest to medical men; and it may be well to direct attention to these now.

The State Board of Charities and the State Charities Aid Association, bodies whose action affects our hospitals and asylums, are expected to have some contention respecting their respective rights and official position. The Charities Aid Association, which has heretofore been dependent on and supplementary to the State Board, now aspires to an independent position, and would have the right of making its reports directly to the governor or legislature. This action is opposed by the older Board. Doubtless the sympathies of most will be with the Charities' Aid Association, since it has proved itself the more independent and vigorous body of the two. It is, however, unfortunate that there should be any antagonism, and, on general principles, it is certainly better to have but one body to supervise our state charities.

The report of the Senate Committee on Lunatic Asylums is to be made this winter, and the action taken upon it will be awaited with great interest.

As New York is one of the states in which pleuropneumonia largely exists, and one whose interests are greatly affected by that and other contagious diseases among cattle, some legislative action should be directed to the subject. The money lately appropriated for investigations of these diseases has disappeared without the securing any scientific results worthy of the name. It would be a wise and liberal measure for our state legislature to authorize a thorough investigation of diseases which so largely interest both science and live-stock owners.

It is like repeating an old story to ask for legal enactments regarding the sanitary inspection of our public schools and other institutions. Nevertheless, there is hardly any subject more worthy of legislation. The establishment of the "doctor in the school-room"—*i.e.*, of some system which would assure to children proper ventilation, freedom from danger of infections, and such provisions in the way of proper light, desks, and text-books, as would prevent the increase of myopia—would be a step forward in civilization.

With regard to medical education it is rumored that an effort is to be made to repeal the law that allows the establishment of medical colleges *ad libitum* in the present easy manner. Should this law be repealed special legislative enactment would be necessary before such colleges could be organized. This might furnish some slight check to the multiplication of institutions already too numerous in the state.

The extension of the medical night service to other cities may possibly take place. A bill for the establishment of such a service in Brooklyn has already been introduced.

The question of vivisection will undoubtedly be actively agitated by Mr. Bergh this winter. That eminent gentleman recently delivered an incendiary lecture on the subject, in which he urged his hearers to sign a petition praying for the abolition of the "hellish practice." We shall have occasion to refer to this matter again.

Attempts will be made by the Sanitary Reform Society to secure some special sanitary legislation, such as a law extending the supervision of city boards of health over plumbing, and a law suppressing the Hunter's Point nuisances.

It will be seen that there may be considerable in the action of our state legislation to attract the attention and interest of the medical profession.

A CAUSE FOR DIPHTHERIA.

Not long since the daily papers gave an account of a family in Montclair, N. J., that had suffered in a remarkable manner from diphtheria, a number of the children having sickened and died within a few days of each other. The affliction of such a visitation aroused the sympathy of the community, and the strange limitation of the disease excited the interest of the public. The latter interest was by no means abated when it was confidently stated that the house and surroundings were in a perfect sanitary condition. But that such a statement was far from correct is proven by the very interesting and instructive account by Dr. J. G. Pinkham, of Montclair, N. J., concerning the cause of the disease in Mr. Crump's

family. Naturally suspicious that there was some local cause for the malignancy of the disease, he was led to study the surroundings from a strictly sanitary point of view, and has been enabled to present some very suggestive and instructive facts. He has made out a very strong case in favor of decomposing matter as one of the causes of this dreaded disease. Seldom, indeed, do we find such straightforward testimony in favor of the point at issue. It would appear that every precaution was taken to keep the house itself in a cleanly and well-ventilated condition. The trouble was, however, on the outside, and the foul air from an adjoining manure pit was carried by the cold air supply-box directly into the bed-chamber occupied by those attacked with the disease. During the period of the greatest malignancy of the disease the wind was from the direction of the compost heap. Only such as slept in the room supplied by the vitiated air were attacked with the disease. These facts were ascertained by Dr. Pinkham in the face of positive assertions to the effect that the sanitary arrangements of the residence in question were above suspicion. How many other similar cases could be brought to light by equally careful examination of the houses which are well appointed and apparently healthy, but in which diphtheria is particularly malignant. It is to be hoped that the intelligent study of the cause of malignancy of the disease in the Crump family may encourage physicians having similar cases to search for like causes.

BERIBERI.

THE disease known as beriberi, or, in Japan, as kákké, has recently appeared in this country at San Francisco, and has been brought for almost the first time within the pale of civilization. This fact and the very interesting pathological characters of the affection make the monograph upon it, just published by Dr. Simmons,* a very timely one.

There have been some contributions to the literature of beriberi, especially by medical men of India, but none which can compare in exhaustiveness or thoroughly scientific treatment with the work just referred to. The various writers upon the disease have given very conflicting views regarding it. Dr. Simmons by no means reconciles all these discrepancies or clears up all obscurities in its pathology. But he has done much in this direction. The disease, however, seems to have somewhat different characters in different localities, and this makes it impossible for a study of it, as it occurs in one country, to answer perfectly for the affection in general.

It prevails in Japan, the East India Islands, South-east India, North-east Africa, and in Brazil. As defined by Dr. Simmons, it is a disease occurring during the summer months. Chronic as to form, but subject to varying degrees of severity, having for its characteristic symptoms anæsthesia of the skin, hyperæsthesia and paralysis of the muscles, anasarca, palpitation, cardiac and arterial murmurs (in the wet form), præcordial oppression, abdominal pulsation, and for its cause a miasmatic, specific soil-exhalation. It has two distinct forms, the wet and the dry, the latter being much the milder.

The investigations of the author referred to regarding the development and special cause of the disease led him to find close analogies between it and malaria. Heat, warmth, and moisture favor its appearance. It is endemic and epidemic in its character, and one attack predisposes to another. A peculiar feature is that it is more apt to attack the robust and healthy. In this it resembles not malaria, but anthrax. Malaria and beriberi often appear together. The utter uselessness of quinine in the latter disease, however, shows that the poisons are distinct.

Beriberi has a prodromal stage which is characterized by general malaise and various indefinite symptoms. This generally runs into the subacute stage. The first symptom here is anæsthesia of the skin over the anterior tibial region, the finger-tips, and around the mouth. This is followed by paralysis of the muscles under the anæsthetic regions, causing extension of the feet and a characteristic gait. Muscular tenderness, palpitation, cardiac and arterial murmurs develop. The disease now begins to show the characters of either the wet or dry form. In the former case œdema of the legs and arms, then a pretty general anasarca, appear. The feet and ankles, however, rarely swell up, and the serous cavities contain but comparatively little fluid. The temperature is normal, the pulse not increased in frequency, but in the wet form is full and compressible. The appetite is but little impaired, the bowels are sluggish, and the urine normal. In the dry form there is no œdema, and the symptoms are in every way milder. A pernicious character sometimes develops in the wet form of the disease, the symptoms then becoming greatly aggravated. Œdematous effusions clog the lungs, and fill up the pleura and pericardium, and death results. Malarial or typhoid fever may occur at the same time in the same patient.

The question of the true pathology of the disease has caused much discussion and has received careful study from Dr. Simmons. The view of most Indian writers is that the primary condition is one of anæmia. Dr. Hebersmith, in a report of the cases occurring at the Marine Hospital, San Francisco, asserts his belief that the primary changes are in the red blood globules which are more or less disintegrated and destroyed. Dr. Simmons gives no data regarding the condition of the blood. He is inclined

* BERIBERI or KÁKKÉ of JAPAN, by DUANE B. SIMMONS, M.D., Shanghai: Inspectorate-General of Customs, 1880.

to refer the pathogenesis of the various symptoms to an action of the specific poison on the vaso-motor and trophic centres. This causes the initiatory anæsthesia, then muscular degeneration and consequent myopathic paralysis. Examination of muscles revealed a degeneration in exact proportion to the extent of the paralysis. The œdema he explains by supposing a paralysis of the smaller blood-vessels, but he more especially attributes it to the dilated condition and muscular degeneration of the heart. The rapid development of these conditions imply that a disturbance in the cardiac nervous supply is a leading cause. Dr. Simmons makes out a stronger case against the anæmia theory than in favor of his own.

The morbid anatomy presents nothing which would not be expected from the symptoms. No positive characteristic changes in the nervous centres have been discovered.

About seventeen per cent. of the cases die and no drugs are known which have an especially marked effect in lessening this mortality. In the wet form cathartics, and even bleeding, are advised. Iron, quinine, and tonics are not useful.

An interesting experiment is now going on regarding the treatment of the disease at the Government Kappé Hospital at Tokio. The institution is divided into two equal parts; in one half, the patients are treated by the "foreign," and in the other by the Chinese system of medicine. The result so far is much to the discomfiture of the disciples of Hoang-ti.

RECENT VITAL STATISTICS OF NEW YORK CITY.

DURING the year 1880 there were in this city 27,536 births, 9,002 marriages, and 31,836 deaths. In 1879 there were 25,573 births, 8,446 marriages, and 28,342 deaths. It will thus be seen that the deaths largely exceed the births, and that our increase in population is due entirely to the influx from outside. The fact that over one-sixth of the deaths occurred in public institutions throws some light upon the cause of this excess in death-rate over birth-rate. A large number of persons just on the verge of pauperism, disease, or crime, drift into the city and speedily pass into the public charge. While there they, fortunately, can not propagate; they can only die.

The number of births to each marriage in 1880 was between two and three, and the per cent. of births to population was about 2.7. This is a much lower rate than should exist, or is generally found under good social conditions. In the English aristocracy, for instance, the birth-rate per family is over four. In all European countries, from which statistics are attainable, except France, the birth-rate is between three and four per cent. of the population. In France alone it is slightly less (2.6) than that of New York city. The proportion of deaths among children under one year of age is extremely large. According to Quatelet, we may expect one-quarter of the infants to die before the end of their first year. In this city, however, the per cent. is 29⅛, or nearly one-third. Nor, as we have asserted before, can this be attributed alone to the excessively hot weather, for the per cent. of these deaths upon births was slightly greater in 1879 than in the past year, the exact figures being .29⅝.

In the statistics given by Routh it is shown that about one-fifth of all deaths are among children under one year of age. In New York city, however, in the years 1879 and 1880 the proportion of these deaths was more than one-fourth.

The number of deaths from zymotic diseases was larger by two thousand in 1880 than in 1879. In this number the deaths from diphtheria are nearly doubled, being 1,459. This increase is offset, however, by a decrease of one-half in the deaths from scarlatina, the number being but 675 in 1880. There may be some significance in the fact that the increase in the mortality from croup kept pace with that from diphtheria.

Aside from sunstrokes, the greatest relative increase in mortality from any single disease was from diphtheria; but the greatest absolute increase, if we except consumption, was in diarrhœal diseases. Here the deaths in 1879 were 2,965, while in 1880 they were 3,960. Of these latter deaths, 3,487 occurred in children under five years of age. And here we see the effects of the hot weather and other causes of mortality that were so active last summer.

There were over 1,500 more deaths from consumption in 1880 than in 1879. The fact is a somewhat curious one, especially as there was no notable increase in deaths from other pulmonary diseases.

We have presented but a partial study of the vital statistics of the city. They have not yet been published in completeness or in official form. The figures, however, from which we have drawn our comments, are very suggestive. Some of them in a tabulated form will be found in another column.

HYDROPHOBIA FIVE YEARS AFTER INOCULATION.—M. Colin has related to the Academy of Medicine a remarkable instance of prolonged incubation of hydrophobia. The man died, after a sickness of two days, with all the symptoms of hydrophobia. Autopsy revealed no lesion whatever; but there were some small scars discovered on the wrist and chest. The man's history showed that he had been undoubtedly bitten by a mad dog five years before. It was said that he had never been bitten since then. How the latter fact could be positively ascertained, however, it is hard to tell. Supposing it true, the ideas suggested by some of M. Pasteur's recent experiments might be brought into use. He found that in chronic cases of fowl cholera the poison remained in some of the organs of the body. It did not enter the general system until by some accident it was led to a rapid development and escape into the blood. Death then followed at once.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, January 6, 1881.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

Drs. Howard, M. D. Mann, Jacob S. Mosher, and J. N. Merrill were made non-resident Fellows.

The Report of the Trustees showed a balance in favor of the Academy of $6,584.

The President announced the reception of $500 from Mrs. John Jacob Astor, as a special donation to the Library fund. Resolutions tendering thanks to the donor, were offered by Dr. Wright, seconded by Dr. Weir, and unanimously adopted by the Academy.

DR. SAMUEL SEXTON then read a paper

ON FALSE HEARING AND AUTOPHONY IN SINGERS, SPEAKERS, AND PERFORMERS ON CERTAIN MUSICAL INSTRUMENTS (see p. 85).

The paper being before the Academy,

DR. D. B. ST. JOHN ROOSA said that he was embarrassed in attempting to speak upon this interesting subject, from the fact that he had had many friendly tilts with the distinguished author of the paper upon some of the points involved, and again because, from lack of time, the cases had not been read; therefore, he was unable to decide whether or not they sustained Dr. Sexton's theories. His remarks, therefore, were general with reference to the important subject. As to nomenclature, he thought "autophony" was an unfortunate name. He thought it did not fully express the symptoms of false hearing, double hearing, and muffled hearing, delineated more or less in Dr. Sexton's cases. However, that was a question for future decision by the profession.

Double hearing and false hearing, as many knew, had been very fully discussed by Sir Everard Home in 1800, who held the view now entertained by Dr. Sexton; namely, that the phenomena were chiefly due to morbid interference with the membrana tympani and the muscles attached to it. Mr. Home did not go so far as Dr. Sexton had in attaching so much importance to the ossicles; but even Mr. Home with a sweep brushed aside the semicircular canals, the vestibule and the cochlea, as having nothing to do with the production of the phenomena of false hearing and double hearing. Before attempting to define double hearing, Dr. Roosa remarked that he had been misunderstood if anything he had written had been interpreted as saying that the cause of this phenomena is entirely in the labyrinth; for he believed quite the contrary. He believed with Dr. Sexton that colds in the head, causing stuffing of the tympanic cavity, closure of the Eustachian tube, suppuration of the middle ear, etc., were the exciting causes of double hearing; but Dr. Sexton and he differed in opinion in this, Dr. Roosa believing that the phenomena are produced by pressure upon central organs rather than by the immediate effect produced by the inflammatory process upon the ossicles and the drum-head. For example: a physician who has disease of the middle-ear, himself an aurist, suddenly observed that he had double hearing in one ear. He had been in the habit of testing himself with the tuning-fork. As is well known, if a person has obstructed middle ear—any condition which increases its resonance—he will hear the tuning-fork better when it is placed against the mastoid process. On the other hand, the tuning-fork is heard worst upon the affected side when the acoustic nerve is affected, either by pressure or original disease.

As soon as this physician had double hearing he heard the tuning-fork worst upon his affected side, quite the reverse of his former condition. Dr. Roosa regarded the case as one favoring his side of the question, as did the gentleman who reported it in the *Archives of Otology*.

In Dr. Bumstead's last edition of his work on syphilis it is stated that if a man hears his own voice he *therefore* has no affection of the acoustic nerve. Dr. Roosa thought he could demonstrate that such is at least a doubtful statement. Take for illustration an example in ophthalmology. If a man is so blind that he cannot go about, yet has sufficient vision left to enable him to distinguish daylight from darkness, shall it be said that he has no affection of the optic nerve? Again, many persons will say that they can count fingers, but it is found that it is the ability to count the fingers upon *their own hand* of which they speak, but they cannot count fingers upon another person's hand. Dr. Roosa thought that some, in the same way, could deceive themselves concerning their ability to hear their own voice, and therefore he had felt that the argument based upon the belief that the lesion in such cases is not in the labyrinth is not completely trustworthy.

Dr. Roosa then cited, as an example of double hearing, a case in which a musician heard C sharp when C natural was sounded, and as his recovery went on the true and the false sound gradually approximated each other and finally became blended. That man had suppuration of the middle ear, but Dr. Roosa believed that this process in the middle ear produced pressure upon the rods of Corti and the basilar membrane, and thus gave rise to the phenomenon mentioned. He did not believe that this beautiful part of the human organism was unaffected in all these diseases. If so, it might be reasonably supposed that there is a part of the human organism which is superfluous.

DR. H. KNAPP thought it best to classify the various forms of false hearing known under the name of pseudocusis, or, more commonly, paracusis, *i.e.*, perverse hearing, according to the fundamental qualities of sound, which are: *intensity*, dependent on the amplitude of the vibrations; *pitch*, dependent on the number of vibrations in the second; and *clang-tint*, or *sound-color*, dependent on the form of the sound-waves. Abnormities of the latter had been mentioned by Dr. Sexton, but Dr. Knapp was unable to find them clearly defined, nor did he remember any well-marked example of this kind from his own experience.

The phenomena of increased or diminished intensity of sounds were caused by abnormal conditions in the sound-conducting apparatus. Autophony in particular was commonly referred to a closure of the Eustachian tube, as had frequently been proved by the demonstration of plugs of false membranes obstructing the tubes or their orifices. It is very common in acute catarrhal otitis, yet it may exist also with the opposite condition, namely, a permanent patency of the tube, as is found in atrophy of the mucous membrane in the so-called dry catarrh, and Dr. Poorten has produced the phenomena even experimentally by introducing a narrow catheter into

the Eustachian tube beyond the isthmus, as far as the osseous part. Some very interesting instances of reinforcement of high sounds from increased tension of the drum-head, and reinforcement of low sounds from paralysis of the stapedius muscle—concomitant with facial paralysis—have recently been reported (Lucæ Moos).

The anomalous perceptions of the pitch of sound cannot be explained by alterations in the conducting apparatus alone. The remarkable phenomenon of double hearing, called *paracusis duplicata* by Sauvages, or *diplacusis* by J. P. Frank—which he expressly mentioned, since the introduction of these words had erroneously been ascribed to him—may be observed in one ear alone, or during the simultaneous function of both ears, and in analogy with the same anomalies of vision he had called them *diplacusis monauralis* and *diplacusis binauralis*. The latter, the commoner and more marked variety, may be imagined as caused by a false tuning of one cochlea or part of one cochlea, so that the vibrating fibres of the membrana basilaris—which may be likened to a stringed instrument, for instance, the piano—are no longer in unison with the corresponding fibres of the other ear. Closure of one, either the good or the bad ear, makes the diplacusis disappear, just as by closure of one eye the binocular diplopia disappears. We may suppose that by an inflammatory process a fibre of one membrana basilaris is either tightened or relaxed, and instead of vibrating, for instance, 200 times in the second it now vibrates 180 times, carrying, however, to the brain the impression of 200 vibrations, as before. If the fibre normally corresponding to 180 vibrations is unchanged, the tone of 180 vibrations will sympathetically excite two fibres, one of which will convey to the brain the impression of the tone of 180 vibrations, the other that of the tone of 200 vibrations. This would be an instance of monaural diplacusis. It will persist when both ears are kept open, or when the healthy ear only is closed, but will disappear when the diseased ear is closed.

Confused hearing, muffled hearing, and the like, may be explained by defective isolation and damping of the fibres of the basilar membrane, when, for instance, the cement between the fibres is softened by imbibition.

All these phenomena relating to anomalies of pitch cannot be explained by abnormal conditions in the middle ear. He agreed with the speaker that they are noticed in cases of otitis media, but must assume that then the inflammation extends to the cochlea, which, in consideration of the vascular communications between the middle and inner ears, is certainly not impossible. These phenomena are, however, quite rare. If they originated in the middle ear we should notice them every day, for the diseases which they complicate are of frequent occurrence.

He agreed further with Dr. Sexton that the treatment should be directed toward the middle-ear trouble, and that the prognosis is favorable, for not only in all the acute cases, but also in the exacerbations of chronic inflammations of the middle ear that were accompanied by diplacusis, had he seen this symptom disappear. In one case the diplacusis lasted nine months, the longest persistence of this symptom that he had observed.

Dr. O. D. Pomeroy believed that, in general terms, the phenomena described by Dr. Sexton depended upon affections of the middle ear. There was no question but that the cochlea was functionally disturbed, and it seemed tolerably clear that middle-ear trouble or disease about the Eustachian tube, etc., was the primary cause. Most of the cases were accompanied by acute inflammation of the tympanic cavity, and recovery took place when the acute disease was cured. Dr. Pomeroy thought that our knowledge of the subject was almost as limited as the subject itself was vast. There was nothing more complicated than the labyrinth of the ear, and he believed that there was very little exact knowledge regarding its pathology. He believed most positively that there was defective tuning of Corti's fibres, and he equally believed that this condition was brought about in some manner connected with increased or diminished density of the fluids of the labyrinth. Dr. Roosa had stated, what every one knew to be true, namely, that we distinguish between deafness due to middle-ear disease and deafness due to affection of the nerve, by placing a tuning-fork upon the teeth; when, if the deafness is chiefly nervous, it will be heard best in the *good* ear; while, if the deafness is due to middle-ear disease, it will be heard best in the affected ear. But lately it has come to be known that there are numerous exceptions to this rule. Sometimes when the drum-head is very much sunken the patient will not hear the tuning-fork as well in the bad as in the good ear. Again, when any foreign substance, as cerumen, or more likely pus, etc., rested upon the oval, or even the round window, and produced pressure, it would cause the patient to hear the tuning-fork badly in that ear, but after cleansing the ear, and inflating in other cases by Politzer's operation, the hearing would be improved, and then very likely the tuning-fork would be heard in the bad ear according to the rule. Dr. Pomeroy believed that otologists had not yet reached a complete understanding of the subject under discussion.

Dr. Holcombe remarked that, in his own case, whenever he had been able to remove from the middle ear the mucus which sometimes collected there, the disagreeable sensation of double hearing had at once disappeared. Whether that fluid pressed upon the foramen ovale or the foramen rotundum he could not say, but his opinion was that the phenomena were due to pressure. At the same time the pressure was not necessarily the result of inflammatory processes; for the tension might be sufficient to press the drum-head toward those windows and produce double hearing. In a conversation, Purkinje, of Prague, had explained to him why the tuning-fork can be heard best on the occiput, and it was because the poles of the cochlea, if continued, will intersect each other at that point.

Dr. Sexton, in closing the discussion, remarked that it was difficult to establish the use of the organ of Corti, or why savages and many animals possess it. Does it separate compound tones? He rather thought that the mental act necessary to their perception and comprehension does not seem to require a cognizance of the separate elements of tones, as it probably receives them as a whole. The combinations, he believed, are made before transmission to the nerve of hearing takes place. He had reported several cases of sudden deafness from syphilis, where it was said by some that the cochlea was affected. That he could not believe as long as such patients could hear their own voice in singing, for even if they retained from habit the ability to sing correctly, the perceptive faculties could not appreciate such tones were they dependent upon the organ of Corti for a musical censorship. These theories regarding the organ of Corti had no better foundation than those attributed to the semicircular canals, where the equi-

librium of the body is said to be maintained. Respecting the latter—the semicircular canals—he had these structures from one ear in his possession, taken from a patient who yet lived and walked as well as any one.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 14, 1880.

DR. H. B. SANDS, PRESIDENT, IN THE CHAIR.

LIGATION OF BOTH FEMORAL ARTERIES WITH THE ANTISEPTIC CATGUT LIGATURE.

DR. BRIDDON presented a patient in whom he had ligated both femoral arteries for the cure of popliteal aneurisms (see p. 93).

THE ANTISEPTIC CATGUT LIGATURE.

DR. LEWIS A. STIMSON then read a paper on the above subject, of which the following is a brief abstract: "The general impression is now favorable to the use of the catgut ligature, and it has seemed desirable to ascertain, if possible, whether this general impression is supported by facts." His examination had been made in two directions, the clinical and the pathological. The first was intended to show the relative success of the catgut as compared with the silk ligature, and the other, to show its local effect upon the vessel to which it had been applied, and thus, perhaps, to indicate the cause of such difference as might be found to exist.

With reference to the first point, statistics were adduced concerning the results of the application of a *silk* ligature to different vessels in their continuity.

To obtain similar statistics of the use of the *catgut* ligature, he had obtained the integral statistics of certain surgeons, and the list was of cases furnished, with a single exception, by seven members of the society, and included 29, divided as follows: Common iliac, 1; external iliac, 3; femoral, 9; common carotid, 5; subclavian, in three parts, 3; brachial, 1, and lingual, 7. All the operations except those on the lingual and brachial arteries were performed for the relief of aneurism, and all the patients, except one, survived. In no case did secondary hemorrhage occur, and in only one case gangrene, which was dry in character.

The difference between the results obtained by the use of the catgut ligature, and those which followed the use of the silk ligature, was so extreme against the latter that it was thought unnecessary to tabulate them in detail. If the statistics given of the results of the use of catgut were sufficiently numerous to eliminate the chance of error arising from the possibility that a short series of cases might be exceptionally successful, it would scarcely be worth while to look for further proof of the superiority of this ligature; but, in view of that possibility, and also of some interesting cognate points, he referred to the anatomico-pathological details furnished by specimens from the human subject and by experiment upon animals. Those, he thought, showed that the probability of secondary hemorrhage was less because occlusion of the vessel was effected, not without its complete division, as had been claimed, but by a purely productive process of tissue-formation provoked by the minimum of irritation and unaccompanied by ulceration. Furthermore, as the presence of a blood-clot was not necessary to the safety of the patient under these circumstances, the proximity of a collateral branch did not add to the risk. The specimens bearing upon that point were *ten* in number.

Dr. Stimson's recapitulation upon these was as follows: "Here are three arteries completely divided by a catgut ligature without suppuration. Two of them present an appearance which indicates that if the patient had survived for a longer time they would have resembled the fourth, in which the continuity of the artery is apparently preserved. Therefore, the fact that arteries examined several months after ligation have preserved this apparent continuity is not a proof that they have not been divided. More than that, in the absence of microscopical proof to the contrary, these three specimens must be taken to show that the catgut ligature does, as a rule, divide the artery completely. This view is in accord with the one expressed by Mr. Bryant in a paper contained in the eleventh volume of the Clinical Society's Transactions, 1878, and supported by four specimens, of which he gives drawings.

"My own examination, which was made in ignorance of his paper, has only confirmed his opinion, and brought out some additional facts showing an intermediate stage in the process which explains the error to which specimens examined at a later period after the operation have given rise."

With reference to the ligature itself, and its mode of application, Dr. Stimson regarded it as a very important question whether or not the ligature should be tied with force sufficient to divide the inner and middle coats of the artery. He did not accept Mr. Barwell's view that the coats of the artery should not be divided; that the knot should be drawn with just force enough only to arrest pulsation beyond it, upon the theory that pressure of the ligature was sufficient to provoke an adhesive process that would completely unite the opposed surfaces of the inner wall of the artery, and that as the integrity of the coats was not destroyed the chance of the occurrence of secondary hemorrhage was diminished. For pressure did not always produce adhesion; nor was the integrity of the coats of an artery maintained under a ligature whenever the ligature was tough enough to maintain its pressure for a day or two. Finally, Dr. Stimson believed that we should still prefer the single round cord, applied with sufficient force to divide the middle and inner coats, because it was more certain to accomplish the object of the operation, and because the danger of secondary hemorrhage does not appear to be sufficiently great to make it worth while to incur the risk of failure to accomplish the principal object of the operation that is involved in the proposed modification.

DR. ERSKINE MASON referred to a case, additional to Pemberton's, quoted by Dr. Stimson, in which Dr. Stephen Smith ligated the carotid artery with an antiseptic catgut ligature that was cast off as is an ordinary silk ligature.

DR. R. F. WEIR referred to one point in which his experience did not accord with Dr. Stimson's, and it was with reference to the duration or solubility of the catgut ligature. In the earlier times of antiseptic treatment, his practice was to sew up wounds with catgut suture, and frequently had seen stumps gape from absorption of the suture within two or three days. Since then he had used the carbolized silk, though Lister, who suggested it, was yet experimenting to obtain gut that will endure longer in a wound.

Again, with reference to the absence of phlebitis after ligation of an artery, he had had a case in which he ligated the popliteal artery for hemorrhage

from a gunshot wound—ligaturing the artery above and below—and the vein let alone. Phlebitis ensued, and extended down the leg to some distance. The wound was dressed antiseptically.

Dr. Briddon had noticed a fact which he had not seen mentioned in any surgical work, namely, "if a large vein is exposed in a wound to atmospheric air for a short period of time, thrombus is formed in that vessel." He had noticed it repeatedly, without injury being done to the coats of the vein other than that attending the exposure.

Dr. Lange remarked that in operations on the neck and in the axilla, where large veins were exposed, sometimes for several inches in length, he had not observed the formation of thrombi, nor had he seen such an occurrence recorded.

Dr. Weir asked whether it was not conceded that the occlusion of arteries with acupressure needles was not due to adhesion and obliteration of the lumen of the vessel without division of the internal and middle coats.

Dr. Stimson replied that, so far as it had been tried, it was very seldom adhesion occurred.

When applied immediately after division of the vessel, as for example after amputation, adhesion did occur.

Dr. J. C. Hutchison remarked that he had experimented with acupressure upon sheep, and succeeded in occluding veins simply by placing their walls in contact without division. He had not, however, applied the needle in the continuity of an artery, and had seen it so applied only in one instance, and that was a case in which Dr. Little applied the needle to the femoral artery for the cure of a popliteal aneurism. The needle was kept in position *four* days, and when removed pulsation at once redeveloped in the tumor. After amputations he had applied the needle in many cases, and the vessel had uniformly been occluded. In several cases he had applied the needle in the continuity of an artery that had been divided, and with entirely satisfactory results. For example, in obstinate hemorrhage occuring after amputation of the breast, where the cut end of the bleeding artery could not be secured, pressure made at some distance from the point at which the hemorrhage occurred, arrested the flow of blood and the artery was occluded.

Dr. R. F. Weir called attention to the superior quality of the catgut ligature obtained in New York, when compared with that which is imported, especially when made, as suggested by Dr. Briddon, from E violin strings (No. 70) for ligatures, to be obtained at Sonntag's, 9 Park Place, or for smaller arteries or for sutures, from the Swiss catgut imported by Keller & Co., 64 Nassau street.

The President remarked that the slight mortality in the cases mentioned by Dr. Stimson was remarkably encouraging; yet, as the author of the paper had observed, the number of cases was too small to guard against possible fallacy. It would be interesting to ascertain, if possible, the causes of success. Some of the members, doubtless, would recall the statement made by the late Mr. Syme that he had tied the femoral artery thirty-three times in succession without accident. In these cases the freedom from accident was perhaps due to his superior skill in operating—disturbing the tissues no more than was absolutely necessary for the application of the ligature. The President thought it possible that one reason for the small rate of mortality in the cases referred to by Dr. Stimson might be found in the superiority of the catgut employed as ligatures.

In three cases in which Dr. Sands had applied the catgut ligature he had used the E violin string, as recommended by Dr. Briddon, and regarded this as superior to any other catgut ligature he had ever seen. It seemed to him that statistics were hardly necessary to prove that when properly selected and applied, catgut is superior to silk as a ligature, because, as Dr. Stimson had stated, a silk ligature always sets up an ulcerative process which must be attended by a risk of secondary hemorrhage that can never be exactly estimated, whereas the catgut ligature does not interfere with immediate and complete closure of the wound.

A case in which Dr. Sands ligated the carotid artery two weeks ago showed the superiority of the catgut ligature over silk, in the fact that there was no ulceration produced, and the healing process was very rapid and complete. The case was one of orbital aneurism. The operation was absolutely uncomplicated. Neither spray nor drainage-tube was used. The wound was washed with carbolized solutions and closed with silver-wire sutures. Primary union, both deep and superficial, took place, and not a drop of pus was observed. Two weeks after the operation he was able to distinguish the occluded artery as a firm, fibrous cord two inches long. Such a result as that would not have been possible after using a silk ligature, inasmuch as two weeks would have elapsed before the separation of the silk ligature, and in the meantime more or less ulceration and suppuration would have taken place. Dr. Sands thought that the greatest future success would probably be obtained by procuring a suitable animal substance for use as a ligature, one that would neither act as a foreign body, nor dissolve prematurely in the secretions of the wound.

Dr. Briddon had ligated the femoral artery fifteen times successfully. In ten of the operations he used the silk ligature, and it gave him a great deal of anxiety and trouble. In five of the operations he employed the antiseptic catgut ligature, and it had given him no trouble whatever. In only one of the five cases was more than a single dressing employed, which was done as a precaution rather than a necessity.

CARCINOMA OF THE FLOOR OF THE MOUTH.

Dr. Lange presented a patient and narrated the history of his case as follows: A German over sixty years of age, came with a tumor as large as a small hen's egg in the floor of his mouth, which Dr. Lange regarded as carcinomatous in character, originating in the sublingual gland, and proposed to operate for its removal. He first ligated both lingual arteries and then divided the lip and lower jaw in the middle according to the method recommended by Sédillot. The patient took chloroform badly; indeed after a few inspirations syncope occurred, the pulse disappeared, the pupils were widely dilated and it took half an hour to revive him, when ether was employed and the operation completed. A number of infiltrated glands were encountered in the submaxillary region, and he, therefore, prolonged his incision along the lower jaw to the border of the sterno-cleido-mastoid muscle. He then separated the soft parts from the inner surface of the lower jaw, and removed the diseased tissues as far as possible—glands and connective tissue, including a portion of the deeper tissue of the tongue. He united the bone according to Martini's method, by boring holes and joining the pieces over an ivory nail. He obtained neither first intention in the soft parts nor solid union of the bone.

There was considerable sloughing of the soft parts, probably due to debility of the patient's circulation, and on the eleventh day secondary hemorrhage occurred. Dr. Lange thought that it came from the lingual artery. Five days later he found his patient almost dead from loss of blood, which came suddenly and in a very large stream, and probably two quarts escaped from the bleeding vessel. He regarded it as a case of secondary hemorrhage due to erosion of the common carotid in connection with the extensive sloughing of the soft parts, and at once proceeded to tie the artery without administering ether. The vessel was situated very deep, due to the thickness of the neck and the pronounced curvature of the spine behind the sterno-cleido-mastoid muscle, and while securing it Dr. Lange injured the jugular vein, and for two inspirations he heard the disagreeable sound accompanying the introduction of air into veins. The opening in the vessel was closed with a ligature applied laterally. The patient gradually rallied, and was, at the time he was presented, in very fair general condition. The tongue was slightly adherent on the under side in front, and its movements were somewhat restricted. There was some necrosis of the lower jaw, and partial pseudo-arthrosis, and the lower jaw did not articulate correctly with the upper jaw, because of its diminution in size. While ligating the left lingual artery, he injured the hypoglossal nerve, and perhaps the difficulty in moving the tongue was due partially to that fact. The pulse had not returned in the temporal and maxillary arteries. There was no impairment of vision or intelligence, and there was no headache. There also was some enlargement of the glands at the angle of the jaw on the right side.

CYSTO-ADENOMA OF THE SUBLINGUAL GLAND.

Dr. Lange also presented a non-malignant tumor (cysto-adenoma) of the sublingual gland which he removed two years ago.

AIR IN THE VEINS.

Dr. Hutchison referred to a case in which air entered the median basilic vein in considerable quantity, and without bad effect either at the time or subsequently. That fact raised the question as to whether or not the danger from the introduction of air into veins had not been magnified.

The President referred to a case in which he lost a patient upon whom he was performing tracheotomy in Bellevue Hospital. He opened the left inferior thyroid vein in the midst of a cancerous mass overlying the trachea; the patient took two inspirations and then suddenly died. He supposed that the effect produced depended upon the amount of air inspired and the rapidity with which it was introduced.

LAPAROTOMY FOR THE RELIEF OF HERNIA.

Dr. Erskine Mason narrated a case as follows: On the 14th of November, 1880, he was called to see a woman sixty years old, with the following history: She had had double hernia for thirty years, had worn a truss most of the time, and at times had considerable difficulty in reducing the hernial tumors. On the 11th of November both masses came down behind the truss. They were about the size of a walnut and were readily reduced by the patient, who noticed nothing wrong in the operation which she had previously performed many times. In the afternoon of the same day she was seized with pain in the abdomen and some vomiting, which continued through the afternoon and evening, and, although it had abated somewhat, she sent on the next morning for a physician who saw her between eight and nine in the evening, when she complained of pain, constipation, and vomiting. A cathartic pill, morphia and atropia, and an enema were ordered. On the morning of the 13th there was less pain than on the previous evening, but vomiting occasionally occurred. During the day she took three cathartic pills, with occasional doses of morphine, and the enema was repeated. On the morning of the 14th her symptoms were unchanged, except the existence of tympanitis, and Dr. Mason saw her at 3 P.M., when he found her pulse 70, tongue moist, abdomen somewhat tympanitic, pressure over the iliac region elicited pain, more marked upon the right than upon the left side, and she was constantly regurgitating a greenish fluid. He was unable to detect the presence of any hernial tumor, and thought she was suffering from reduction of a hernia *en masse;* but which one he was unable to determine. Dr. Mason proposed laparotomy, which was readily accepted by the patient and her friends, and the operation was performed at five o'clock in the afternoon, assisted by Dr. Briddon.

An incision was made in the median line only sufficiently large to admit three fingers, which were passed down upon the left side, and nothing was detected. On the right side, however, just above Poupart's ligament, he detected a small mass which seemed to be held to the anterior wall of the abdomen by slight adhesions, and by very slight pressure the knuckle of intestine slipped as it were from under a band. The intestines were only moderately congested. He passed his fingers into the femoral sac from within and found that it was empty. The operation was done with full antiseptic precautions. The patient had a comfortable night, and on the following morning had scarcely any pain. Her temperature was 98½° F., pulse, 93, but the tympanites remained the same as before the operation. The urine was quite copious and was drawn several times. No movement from the bowels. Dr. Mason then noticed a slight twitching of one side of the patient's face, and of the arm of the same side, and slight vomiting still continued. In the evening the twitchings were more marked than in the morning, and affected the whole side. Vomiting ceased about ten o'clock on the night of the 15th. The doctor then drew off the urine, and found that its specific gravity was 1014, and it was also albuminous. The twitchings continued until the morning of the 16th, when the patient became comatose and died at 1.30 P.M. A few hours before death the bladder contained four ounces of dark-colored urine, which was albuminous. No autopsy could be obtained.

SCIATICA—NERVE-STRETCHING.

Dr. Lange narrated a case of sciatica, which had been treated in a great variety of ways without benefit, and the patient came to him for an opinion with reference to the operation of nerve-stretching. For purposes of diagnosis he resorted to forced flexion of the thigh upon the trunk, while the leg was fully extended upon the thigh and the foot flexed upon the leg. The manipulation gave the patient excruciating pain, which was described "as if a bullet had been shot from the sole of the foot through the limb to the hip." It was decided to resort to the operation of nerve-stretching, but the pain in the limb began to subside soon after the forced movement, and the patient was soon well. Dr. Lange thought that a kind of nerve-stretching had been

done by the manipulation, and suggested that the method might be adopted in other cases.

Dr. Weir referred to the statements of Mr. Hood, of London, who said that forcible measures of a similar kind would occasionally relieve pain.

Dr. Lange also exhibited an instrument devised for holding the foot in proper position while plaster or other dressing was being applied after tenotomy and *rétrécissement forcé*.

The society then adjourned.

Correspondence.

ANIMAL LIGATURES—A HISTORICAL NOTE.

To the Editor of The Medical Record.

Sir—In looking up another matter, in old journals, I came across the following item from the *Southern Journal of Medicine and Surgery* (September, 1847), which was to me, unacquainted with the literature of the subject, a revelation.

If you think it of any historical value, please give it circulation.

"Dr. W. S. Wragge, in a paper on the use of animal ligatures, states that he has been in the habit of using these ligatures for upward of ten years, and for several years he has used none but these. In the course of this period he has tied the arteries of the fingers, hand, forearm, arm, leg, and thigh, and he has never seen any symptom result from which he could infer that the knot had not been removed by absorption. From the facts he has observed he deduces the following inferences: 1st, that the deer-sinew ligature, if properly applied, will effectually arrest hemorrhage from vessels even of large size; 2d, that they produce less inflammation of the living tissues with which they are placed in contact, during the time they remain as foreign bodies in these tissues, than other substances; 3d, that they are susceptible of being absorbed and carried away by the action of the living parts in the midst of which they are placed."

John L. Neilson.

Brooklyn Naval Hospital,
January 5, 1881.

OVARIOTOMY WITHOUT ANTISEPTIC PRECAUTIONS.

To the Editor of The Medical Record.

Sir—In the October number of the *Am. Jour. of the Med. Sciences* Prof. Wm. Goodell furnishes an article on "Four Cases of Ovarian Tumor and one of Fibro-Cystic Tumor of the Womb operated on under the Spray."

It is evident that the author is thoroughly committed to the antiseptic method of treating wounds—so much so that failure of success is attributed more to the want of minute enforcement of "Listerism" than to any other one cause, or, perhaps (I infer), from all other causes combined. Were it not that such an eminent authority advocated such unreserved opinions, I should feel like leaving the questions of antiseptic or non-antiseptic treatment of wounds to the more certain judges, time and experience. But since facts, obtained from actual practice, are the best answers, I will briefly mention my experience for the past twelve years. I was also enthusiastic in my advocacy of the antiseptic methods of treatment, of all kinds of wounds, as proposed by Mr. Lister. I then believed that much of my success, or I should, perhaps, say the satisfactory issue of my cases, was due to the triumphant combat between atoms of carbolic acid and destructive (?) organic germs. I tried the method thoroughly because I believed in it. Now it is germane to ask why are my views quite opposite from those previously entertained? Because, in my experience, what I consider excellent results are not obtained under the antiseptic management. I have operated for removal of ovarian tumors of different textural arrangement twenty-six times, and of that number twenty have recovered. In six cases, in my early experience, when I used minute atomization faithfully, the mortality was three cases, or fifty per cent. After I discarded the "anti-germ" treatment the mortality, as is shown by the remaining twenty cases, became notably less.

Within the year just closing I have made five operations, one of which was for removal of a large fibro-cyst, and of the remaining four, two were multicystic, with extensive adhesions, and two large simple cysts. Two of the cases were operated upon before a class of two hundred students (many of whom were in daily attendance upon dissections). Recovery without a single complication. In the case operated upon six weeks since one of the attendants, upon being directed to obtain a blanket, unintentionally went to a part of the hospital where unwashed clothing was kept, and brought a blanket—which had been covered over a dead body—that was used as a covering in conveying the patient from the amphitheatre to the room for subsequent treatment. The other cases were operated upon in private, but in each instance physicians, numbering in one case fifteen, were not interrogated as to the kind of cases under treatment in their respective practices. No peritonitis—I mean general—occurred. It is understood that there must always be some inflammation at the part of the peritoneum compromised by the warmth and sensitive apparatus. In none of the late cases was any other local treatment employed than dry dressing and pressure, which was permitted to remain unremoved from four to eight days. The pedicle usually ulcerated and sloughed, the clamp in from fourteen to seventeen days. In three of the cases organic material (ligatures) was left within the abdomen. For a period of eight years I have both practiced and taught what I believe—the unsurpassed principles of dry dressings and properly administered pressure. In fact, I feel satisfied that the longer a wound can remain undisturbed, without the products of inflammation reacting upon the parts, the better will it be for the reparative process. Where the wound is from choice or necessity an open one, drainage outward into a *not* to be *frequently removed* dressing results, in the direction of speedy repair, will be obtained which cannot be imitated by the advocates of "frequent dressings" and "Listerism." Now, if my experience is correct, are not the exceptions too many to warrant Prof. Goodell, and those who believe as he does, to insist upon the universality of his rule? Yours truly,

W. F. Peck.

Davenport, Iowa.

LIME-WATER IN DIPHTHERIA.

To the Editor of The Medical Record.

Sir—I learn with some surprise from Dr. Jacobi's communication in to-day's Record, that he still fails to agree with me on the lime-water question. If I "deplore" this less than its intriusic importance

demands, it is because I yet have good reason to believe that the ink I have shed in the advocacy and defence of a valuable therapeutical measure has not been wasted.

With regard to the question between us of relative originality, I cheerfully accept Dr. Jacobi's claim to have "advised" the profession in 1875 "what" (drugs) "to use, and how often"—those drugs being the very ones which most of us had long been using, and the principle of frequency in their administration being then far from new, either to medical practice or literature. In 1876 I stated before the New York Academy of Medicine with what combinations of these common and standard remedies, with what modes of application, and with what principles of management of cases I had obtained excellent results, which results from which method have since been repeated and attested by very many other physicians. In the RECORD of February 23, 1878, I stated in reply to the same claim which Dr. Jacobi now reiterates, the fact well known to many physicians at the Demilt Dispensary and others, that I had employed and advocated the use of essentially the same method of treatment which I subsequently published for two years before Dr. Jacobi's paper appeared, and absolute proof that I had employed that exact method in all its details several months before that date.

If the profession, who certainly "have eyes," have failed to accept Dr. Jacobi's advice on the treatment of diphtheria at his own estimate of its relative importance and value, this may naturally account for the "wounded self-esteem" to which he so pathetically alludes; but it is hardly just that he should visit its results upon me, who have on all suitable occasions mentioned his paper with cheerful commendation.

If there has appeared in the little discussion which is now, I fondly trust, concluded, anything like a "quarrel" or disposition thereto, I can safely appeal to the readers of the RECORD that it has not been on my side. Dr. Jacobi now expresses his preference for the avocations of peace, which is, under the circumstances, both natural and commendable. Rejoicing to learn of this new point of agreement between us, I remain yours very truly,

C. E. BILLINGTON, M.D.

NEW YORK, January 15, 1881.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 9, 1881, to January 15, 1881.

MEACHAM, F., Capt. and Asst. Surgeon. Assigned to temporary duty at Ft. Niagara, N. Y., during absence, on leave, of Asst. Surgeon Price. S. O. 6, Department of the East, January 10, 1881.

PRICE, C. E., Capt. and Asst. Surgeon. Granted leave of absence for one month and ten days, to take effect on arrival of Asst. Surgeon Meacham at Ft. Niagara, N. Y. S. O. 2, Middle Division of the Atlantic, January 10, 1881.

COMEGYS, E. T., Capt. and Asst. Surgeon. Granted leave of absence for four months on surgeon's certificate of disability. S. O. 4, A. G. O., January 7, 1881.

BURTON, H. G., First Lieut. and Asst. Surgeon. Now awaiting orders at Boston, Mass., to report in person to the Commanding General, Department of the East, for assignment to temporary duty. S. O. 7, A. G. O., January 11, 1881.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 15, 1881.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Jan. 8, 1881.	0	14	179	6	30	168	20	0
Jan. 15, 1881.	0	12	171	6	36	129	10	0

HOSPITAL FOR THE RUPTURED AND CRIPPLED, FORTY-SECOND STREET AND LEXINGTON AVENUE.—A graduate in medicine is wanted to fill an unexpired term, as Junior Assistant, from February to June, 1881. Two vacancies in the Junior Assistantship will occur in May. Term of service two years, dating from June 1st. Only those who have served in a general hospital need apply. Applications can be made to Dr. James Knight, at the hospital, prior to May 1st, from 9 to 12 A.M.

EAST RIVER MEDICAL ASSOCIATION.—At the annual meeting, held at Dr. I. M. Lang's, 294 East Broadway, on Tuesday evening, January 11th, the following officers were duly elected: *President*, Dr. James R. Taylor; *Vice-Presidents*, Dr. T. C. Finnell, Dr. Martin Burke; *Recording Secretary*, Dr. Wm. I. Purcell; *Corresponding Secretary*, Dr. H. E. Crampton; *Treasurer*, Dr. Veranus Morse. Recent amendments to the constitution have greatly improved the efficiency of the Association. Its membership is limited to forty, and its ranks are full.

THE AMERICAN MEDICAL BI-WEEKLY.—This journal, which was formerly published in Louisville, Ky., and which had nearly reached the close of the eleventh volume when the severe and protracted illness of the editor compelled its temporary discontinuance, is now, on his entire recovery, restored to its position among the medical journals of this country. The editor, Dr. E. S. Gaillard, having made his home in New York, the Bi-Weekly is now published here. It is now a double-column medical journal, larger than the old Bi-Weekly, and is published at one dollar a year.

NEW YORK PATHOLOGICAL SOCIETY.—The following officers have been elected for the ensuing year: Dr. T. E. Satterthwaite, *President;* Dr. L. A. Stimson, *Vice-President;* Dr. Wesley M. Carpenter, *Secretary;* Dr. John H. Hinton, *Treasurer;* and Dr. John C. Peters, *Editor of the Transactions.*

DR. JOHN CLAY still clings to his Chian turpentine, and asserts that it will, better than any other drug, relieve pain, prevent hemorrhage, and, in some cases, stop the progress of cancerous growth or make it disappear entirely. He says that the two cases which he first reported in the *Lancet* are still living and have had no return of the growth, though it is now over a year since they left Dr. Clay's care.

ANOTHER SUCCESSFUL NEPHRECTOMY for pyonephrosis has been performed by Mr Cooper, the case being reported to the Hunterian Society of London. This

makes the third successful case that has been performed in England during the past year. The operation seems to be growing in favor. The most rational and successful method for most cases is the extra-peritoneal or lumbar, a transverse instead of longitudinal incision being made. Mr. Couper operated in this way.

THE CINCINNATI MEDICAL COLLEGES.—An attempt is being made to consolidate all the medical colleges of Cincinnati into one college, to form the medical of Cincinnati University. The attempt to do this has been made before, and although the present effort is a stronger and more serious one, it does not seem likely to be successful.

MEDICAL LEGISLATION IN MICHIGAN.—The Southern Michigan Medical Society, at a recent meeting, adopted two series of resolutions, one recommending the enactment of a law regulating the practice of medicine, and the other appointing a committee to memorialize the legislature on the subject of a supply of dissecting material.

FOOT-AND-MOUTH DISEASE is prevailing among English cattle. It is suggested that cremation be applied to all that die of the disease. It causes more injury to cattle than pleuro-pneumonia and splenic fever together.

FATAL ALCOHOLIC POISONING.—A man in this city drank, on a wager, three pints of whiskey at a sitting. Symptoms of collapse soon appeared, and he died in a short time.

THREE DEATHS FROM CHLOROFORM are reported as having occurred in November and December last. One of these was in Ballard County, Ky., one in Guy's Hospital, London, and one in Billroth's clinic, at Vienna.

PHILADELPHIA MEDICAL SOCIETIES.—The annual election of the College of Physicians of Philadelphia has resulted in the choice of the following officers for 1881: *President*, W. S. W. Ruschenberger; *Vice-President*, Alfred Stillé; *Secretary*, R. A. Cleemann; *Treasurer*, Chas. S. Wurts; *Curator*, T. Hewson Bache; *Librarian*, Robert Bridges; *Recorder*, J. Ewing Mears.

THE officers of the Philadelphia Academy of Surgery are: *President*, S. D. Gross; *Vice-Presidents*, D. H. Agnew and R. J. Levis; *Secretary*, J. E. Mears; *Treasurer*, William Hunt; *Recorder*, John B. Roberts; *Corresponding Secretary*, Thos. G. Morton.

CHIAN TURPENTINE.—The medical committee of the Middlesex Hospital have passed a resolution to the effect that as the result of prolonged and careful trial with Chian turpentine in the treatment of cancer, the drug has proved utterly worthless. This conclusion is in harmony with general experience elsewhere.

COMPARATIVE ANATOMY.—In *Science* for December 31st, is an interesting paper over initials which are not difficult to be interpreted as belonging to Professor Burt G. Wilder, relating to recent American papers on Comparative Anatomy. To those who have not followed the recent researches of Professors O. C. March and E. S. Morse a perusal of this paper is recommended, as the salient points are there given. The same writer also describes some recent papers by Dr. H. C. Chapman, of Philadelphia, on the "Placenta and Generative Apparatus of the Elephant," and on the "Structure of the Orang Outang." Dr. Spitzka also, in a letter in the same journal, raises various objections to the last paper, chiefly relating to the structure of the brain. As far as we can judge the chief point of difference between Dr. Chapman and his critic appears to be, viz.: 1, direction of the fissure of Sylvius; 2, relative position of the cerebrum and cerebellum, as described by Dr. Chapman, distorted by imperfect manipulation; 3, presence of convolutions in the Island of Reil of the orang; 4, general richness of gyri in the anthropoid brain; 5, comparative position of the fissure of Rolando in the anthropoids.

VITAL STATISTICS OF NEW YORK CITY FOR 1878, '79, '80.—The following table shows the causes of death in New York in 1880 compared with statistics for 1879 and 1878:

	1880.	1879.	1878.
Zymotic diseases	9,943	7,994	7,648
Constitutional diseases	7,218	6,416	6,436
Local diseases	11,367	11,079	10,213
Developmental diseases	1,978	1,848	1,701
Deaths by violence	1,360	1,004	1,010
Small-pox	37	25	2
Measles	478	244	270
Scarlatina	675	1,477	1,099
Diphtheria	1,459	671	1,007
Croup	946	522	499
Whooping-cough	285	577	582
Erysipelas	167	145	145
Typus fever	4	4	4
Typhoid fever	247	178	245
Miasmatic fever	550	590	561
Yellow fever	1	2	0
Cerebro-spinal meningitis	156	108	97
Diarrhœa diseases	3,960	2,965	2,945
Diarrhœal diseases in persons under five years old	3,487	2,592	2,598
Alcoholism	229	198	127
Rheumatism and gout	175	171	140
Cancer	686	572	570
Consumption	5,868	4,543	4,466
Bronchitis	1,441	1,293	1,184
Pneumonia	2,976	2,354	2,228
Heart disease	1,192	1,164	1,068
Marasmus and scrofula, etc	740	646	588
Hydrocephalus	623	609	604
Meningitis	642	568	612
Convulsions	746	646	691
Apoplexy	487	489	447
Insolation and prostration	116	41	52
Cerebral and nervous diseases	2,732	2,485	2,410
Bright's disease	1,473	1,348	1,161
Surgical operations	72	39	21
Drowning	256	149	185
Puerperal diseases	431	359	360
Suicide	155	117	142

VACCINATION IN NEW YORK.—Forty-five thousand persons were vaccinated last year by the officers of the Vaccinating Bureau, under the direction of Dr. J. B. Taylor. The vaccine is obtained from calves at Clifton, N. J., where from four to six calves are vaccinated every week.

The receipts from sales at the Vaccination Bureau during the month of December amount to more than $600. The virus is sent to every state in the Union and abroad. The points and crusts are wrapped in paper and sheet rubber, and are transmitted by post and express.

There is always enough virus at the Vaccinating Bureau to vaccinate from 5,000 to 10,000 persons, and an order for 10,000 "points" could be filled very quickly. The price charged for "points" is $1 for eight. Crusts are worth more. A discount is made when officers of health departments or institutions give an order. It is not possible to estimate the number of vaccinations performed last year by private physicians and individuals. In the Vaccinating Bureau the percentage of successful vaccinations is ninety-five.

MAN IS A PHYSIC-TAKING ANIMAL.—In England the patent medicines consumed would, if equally distributed, give over half a bottle or box to each in-

habitant annually. And to this must be added the pills and mixtures given by the faculty. In America the amount of drugs taken is even greater than in England.

Cod-Liver Oil and Bromides.—Dr. C. M. Jordan, of Fargo, D. T., writes: "Referring to the letter of Dr. Fairbairn in the Medical Record of December 11, 1880, permit me to say that the practice of using cod-liver oil in connection with bromides is not new. While pursuing my medical studies I was taught to place considerable stress upon the use of cod-liver oil in connection with mercurials, iodides, or bromides, when used as alteratives; not on account of its therapeutical value, but as a food to supply the deficiency produced by the action of the drug on nutrition, the oil not counteracting the action of the medicine as it affects the morbid condition, but prevents the appearance of symptoms produced by the medicine itself, indirectly, by restoring the tissue-waste caused by the long-continued use of the drug."

Dedication of a New Hospital for Children.—The new St. Mary's Free Hospital for Children, at Thirty-fourth street, near Ninth avenue, was dedicated with appropriate exercises, on Thursday, December 23d. It has been erected on a plot of ground formerly occupied by a smaller institution of the same character, in charge of the Protestant Episcopal Sisters of St. Mary. The new hospital has a frontage of fifty feet, and is sixty-five feet deep, exclusive of a rear extension measuring forty feet. It is four and a half stories in height, and built of pressed brick, and trimmings of light brown stone.

The entire interior is finished in polished ash, the flooring being of hard pine. Particular attention has been given to the plumbing arrangements throughout the building. The pipes leading to and from all closets, basins, and sinks have been left entirely exposed, so that when a leakage occurs, or anything in connection with the plumbing system gets out of order, the defect can be readily detected and remedied. Every floor is heated by steam. An elevator, enclosed in brick walls, runs from the basement to the attic. The hospital, which is exclusively intended for the care of sick children between the ages of two and thirteen years, is now open for the reception of patients. It has no permanent fund from which to derive an income, relying for support on the contributions of persons interested in the care of sick children whose parents or friends cannot give them proper attention.

Debate on the Treatment of Typhoid Fever.—An interesting debate upon the above subject took place recently before the Metropolitan Counties' Branch of the British Medical Association. Drs. Halvershon, Bristowe, Kerr, Ord, and others took part. As regards diet, the use of milk was urged to be of chief importance. Dr. Bristowe and Dr. Kerr thought alcohol only necessary in a few cases. Nothing especially new was said about the use of drugs. Dr. Broadbent recommended opium for the relief of tympanitis.

The point chiefly discussed was the utility of baths. Dr. Bristowe doubted their efficacy, and thought that he had had two cases of fatal pulmonary congestion attributable to their use. Dr. Broadbent was feeling a constantly increasing confidence in the utility of baths. Dr. Cayley read some remarkable statistics from the military hospitals in Germany in favor of the bath treatment. Dr. Collie had abandoned the bath treatment as not only useless, but even dangerous. He could not put faith in continental statistics, and thought that many cases of mistaken diagnosis were included in them. Dr. Collie said that out of one hundred cases of typhoid fever, seventy-five would get well with simply good nursing, fifteen would die, and the remaining ten might or might not recover. Dr. Ord had seen good effects from the tepid bath in selected cases of high pyrexia.

Dr. Mahomed spoke in favor of the cold-bath treatment.

The discussion, on the whole, did not much favor the cold-bath treatment in typhoid. It is not an established therapeutic measure in England by any means, and it is doubtful if it ever will be. It has met with scarcely any favor in New York, or this country generally.

Picrate of Ammonium in Malarial Fevers.—Dr. J. B. Wainwright, of Milltown, New Jersey, writes: "Not having seen any mention made in any medical papers of the above remedy, and its effects in malarial fevers, I take this opportunity to express my experience with it. For the past six months malarial fever in its various forms has existed in our community, and having had occasion of seeing and treating a number of cases, I concluded to give picrate of ammonium a trial. My manner of administering the remedy is in pill form, in doses of one to one and a half grains thrice daily, and if found necessary, increasing the dose to two grains. By its use there was a rapid decline in the temperature, a decided fall in the rapidity of the pulse, the tongue became moist, and finally the patient would break out in a profuse perspiration which would be the termination of the attack. In but a few cases did I find it necessary to repeat the treatment at the end of one week. If treatment be begun at the first appearance of the attack, it would most invariably put an end to the progress of the fever. If the ammonium is given in large doses and continued for a few days, the urine becomes of a yellowish-brown, the skin and conjunctiva become yellow; but this discoloration is transient, as it will disappear in a fortnight after the discontinuation of the remedy. There are several advantages to be claimed for it over quinine and other alkaloids of cinchona, inasmuch as it does not nauseate, neither does it produce any tinnitus aurium, and in no case, when the duration of the attack was protracted, did I find that well-known accompaniment, the ague cake.

Explosive Medical Compounds.—The medical and pharmaceutical journals have recorded a number of cases of explosions having taken place by the admixture of explosive substances. Among the prescriptions having given rise to such accidents we will mention the following: 1st. Mixture of hypophosphite of lime, 50 centigrammes; chlorate of potash, 3 grammes 75 centigrammes; lactate of iron, 30 centigrammes. 2d. Solution of glycerine, 8 grammes, in acid chromic, 4 grammes. 3d. Mixture of chlorate of potash, tr. ferri perchlorid. and glycerine has exploded in the pocket of a patient. 4th. Chlorate of potash mixed with catechu and used as a dentifrice, may explode in the mouth of the patient provided hard friction is used. 5th. Pills of oxide of silver (frequently used in England in affections of the stomach) have exploded in the patient's pocket. Pills of permanganate of potash and ferri reduct., pills of golden sulphur of antimony and chlorate of soda, may explode during or after their preparation. It is, therefore, essential to avoid associating glycerine, and, in general, substances easily reduced, with

such oxidizing agents as chromic acid, chlorates, permanganates, and certain organic acids.—*Bull. gén de thérapeut.*

Shock from Vaginal Injection after Labor.—Dr. W. T. Smith, of Hanover, N. H., writes: "I had recently a case of severe shock from a simple vaginal injection after labor. It was a surprise and a very annoying one to me, and I report it as a hint of caution. The injection, which was administered by an experienced nurse, was a weak solution of carbolic acid—one part in two hundred and fifty. The instrument was a fountain syringe, the nozzle having no central aperture. The injection had been used twice before; the first time with comfort, the second time with complaint of irritation near the ostium vaginæ, which I ascribed to incomplete solution of the carbolic acid, and I gave directions that it should be thoroughly mixed. The third time was on the fifth day after labor. The instant the bag of the syringe was raised, after the insertion of the tube, a shock took place. The patient felt "as if the top of her head would fly off." She became livid and greatly distressed, to the extreme alarm of the family. She went into a chill and did not recover for an hour and a half, and it was some days before she regained lost ground.

"The fluid doubtless entered the uterus. The nurse said that she inserted the nozzle, which was four inches long, as far as she could.

"The patient was a multipara, and the labor, though it was a case of twins, had been easy and without complications."

Fracture of Skull, with Exudation of Brain-Substance—Recovery.—We have received from Dr. E. L. Wilkinson, of Van Wert, Ohio, the report of a case which is interesting to surgeons as well as to those engaged in the study of cerebral localization. The patient, a woman aged twenty-four years, was shot in the head, the bullet tearing up a V-shaped portion of the scalp and making a quadrangular opening into the skull, through which the brain protruded. The fracture was situated about the middle of the right parietal bone at its sagittal margin. The protruding cerebral substance and some of the broken bone were removed, the wound dressed with lint, kept moist with a cold carbolized solution, and a mixture containing ten grains of potassium bromide, fifteen minims of the fluid extract of ergot, and two of the fluid extract of digitalis, given every three hours. The injury was followed by complete paralysis of both lower extremities and of the right upper extremity. The scalp suppurated and was kept open to allow the escape of pus. The paralysis gradually disappeared, first in the left lower extremity, then in the right upper extremity, motion returning before sensation. Fifteen months after the injury there was still some paralysis of the right lower extremity, but the patient walked with a slight limp. In conclusion Dr. Wilkinson says: "The old plan of treatment, of protecting the brain with a silver plate, was omitted, and I believe its omission to be a wise one. An unobstructed passage for the free evacuation of the pus accumulating in the wound and on the brain, through sinuses of its own formation, is one of the secrets of the recovery of this case."

St. Paul, Minn., Medical College.—Prof. Alex. J. Stone, President of the St. Paul Medical College, Minn., writes: "Friends of the St. Paul Medical College and of the causes of advanced medical education have been surprised to see, in two issues of your journal, insinuations that the St. Paul school has no students.

"The first item referred to was apparently founded upon an editorial in the *Medical and Surgical Reporter* of Philadelphia, which in itself bore evidences of malice, as it was undoubtedly written *before* the opening of our session, when we *could* have no students. The second notice—in your editorial of January 1st—speaks of our having 'few or no students.'

"While the charge remained buried where it was born, I did not deem it advisable to answer it; but now that it has been given life in your far-reaching columns, and had the honor of your name as sponsor, I am desirous of correcting it.

"The St. Paul College commenced its first year with little advertising, in a frontier state, with the highest requirements of any school in the country, surrounded by lukewarm friends, and a few bitter enemies, with a matriculation of eleven, which has increased to fifteen, with a prospect of further increase within a few days.

"The faculty received many more applications, which were declined unless the applicants would comply in letter and spirit with the regulations as advertised. Although the class is small, as compared with the present classes of eastern schools, yet I believe there are very few of the older colleges that can boast of so large a class during their first year. While we never expect a very large class, nor do we deem such of the greatest value to school or scholar, we do expect an intelligent one, gathered from men with fair preliminary education, and shall not wait for large classes and great pecuniary prosperity before taking another step in advance in the cause of medical education. Knowing your own extreme fairness, I am positive that you will gladly insert this correction. I only hope that other journals will copy this with a semblance of the eagerness with which they copied your charge."

Prof. Wm. Pepper, M.D., Provost of University of Pennsylvania.—Dr. William Pepper, who was, on Tuesday last, elected by the Board of Trustees of the University of Pennsylvania provost of that institution, has sent to the board a letter of acceptance.

Books Received.

ELECTRICITY A PARALYZING AGENT.

PROOFS FROM THE AUTHENTIC EXPERIMENTS.

BY THOMAS W. POOLE, M.D.,

LINDSAY, ONT., CANADA.

THE INTRA-POLAR CURRENT.

1. The action of the common galvanic current is to paralyze that portion of a motor nerve included between the poles or electrodes.

Experiment.—"If a frog be poisoned with strychnia, the characteristic spasms may be averted by subjecting the spinal cord of the animal to the action of a continuous galvanic current; or if these spasms have already made their appearance, they may be at once suspended by the same means" (Matteucci, quoted by Dr. C. B. Radcliffe, Lectures, etc., p. 64). The frogs die, of course, but without any symptoms of tetanus.

Under the same conditions of convulsive spasms from strychnia-poisoning, precisely similar results attend the destruction of the spinal cord. This was originally observed by Magendie and was confirmed by Dr. Pereira, who states, "the destruction of the cord by the introduction of a piece of whalebone causes the immediate cessation of the convulsions" ("Mat. Med.," vol. ii., p. 540). Here, then, *the action of the galvanic current on the spinal cord is equivalent to the destruction of the cord;* which is, surely, a striking proof of its paralyzing action. Other considerations suggested by this experiment will be discussed at a future time.

Experiment.—"If the spinal cord of a rabbit be included in the circuit of a voltaic battery, and the current allowed to pass for *a few moments, the part between the poles* may be cut, pricked, torn, or even exposed to the shocks of a coil machine, without giving rise either to pain or convulsion. . . . Whether the current was passed up the spine or down the spine the result was the same so far as *its paralyzing action* was concerned" (Matteucci, Radcliffe, Ib., p. 64. Italics mine). This is plain and direct proof of the paralyzing action of the galvanic current on that portion of the spine included *within the circuit.*

It cannot be said that these are the exceptional effects of currents of unusual strength. On the contrary, as the experiments show, they are the effects of ordinary currents, such as are commonly used on the human subject, to relieve pain by the "anæsthetic" and "benumbing" effects they produce.

Confirmatory evidence.—Drs. Beard and Rockwell, referring to the effect of the galvanic current on the spinal cord, state: "During the passage of the current no contractions are observed and *a paralyzing effect soon takes place.*" They also refer to the "anæsthetic" and "benumbing effects of electrization" ("Med. and Surg. Elec.," 2d ed., pp. 123-127).

Dr. Moritz Meyer writes: "Valentine was the first to assert that the constant current, so long as it traverses a nerve with a given intensity, renders it *incapable of transmitting contraction-producing stimulus.* . . . Matteucci attained similar results by a different species of experiments. . . . Later, Eckhard made some experiments to discover the effect of the electric stimulus on the nerves of the muscles, when a part of the nerve is subjected to the action of a continued current, and found that in this case contractions followed neither the mechanical nor chemical irritation, nor even the stimulus of the interrupted current. In other words *the nerve is paralyzed,* so long as any portion of it is subjected to the action of a continued current" ("Elec. in Prac. Med.," translated by Hammond, p. 62).

Dr. C. B. Radcliffe writes: "When a motor nerve is acted on by a galvanic current, the part of the nerve which is included between the two poles is very soon paralyzed by the current" (loc. cit., p. 77).

From the foregoing it is evident that the paralyzing effect of the galvanic current over the portion of motor nerve within the circuit, is just as firmly established as any other fact in experimental physiology.

THE EXTRA-POLAR CURRENT.

The motor nerve-trunk passing to a muscle may be subjected to the extra-polar influence of direct and inverse currents.

The direct current.—A long nerve with its muscle attached is prepared. Toward the end of the nerve farthest from the muscle, the poles of a galvanic battery are arranged for the direct current; that is, with the N. pole nearest the muscle.

The electric current itself actually traverses no more of the nerve than is within the circuit, that is between the electrodes. But the *effect* of the current traversing this portion passes down the nerve toward the muscle, a certain distance, proportionate to the strength of the current. The portion of nerve thus influenced (between the negative electrode and the muscle) is in the negative phase of electricity: (catelectrotonus) and *its irritability is said to be increased.* By this it is meant that this portion of the nerve is functionally excited, and in readiness to convey a more active impulse to the muscle whereby the latter may be made to contract.

Let us now see if this conclusion is proved by the experiment relied on for that purpose.

Experiment.—M. Eckhard (to whom this observation is due) ascertained, by repeated trials, the strength of a concentrated salt solution, which, applied near the middle of the nerve-trunk, would just fail to produce a contraction of the muscle. Then by means of a galvanic battery, the electrodes of which were applied to the end of the nerve-trunk farthest from the muscle, the influence of a descending (or direct) current was made to pass through the nerve. It was then found that so long as the current was maintained, and its influence continued to pass down the nerve—that is, during the continuance of catelectrotonus—the same salt solution which failed before now sufficed to produce a contraction of the muscle. Hence the inference that the irritability of the nerve is increased by the direct galvanic current.

In more recent experiments of this kind the poles of an induction battery are substituted for the salt solution, and it is found that an induced current which just failed before, succeeds in causing the muscle to contract so long as the nerve is subjected to the direct galvanic current, as in the previous case (Dr. M. Foster, "Handbook Phys. Lab.," p. 389). The principles involved in the two experiments are precisely similar, and the inference drawn, as stated above, is the same, namely, that by the action of the

direct current the irritability of the nerve is increased.

Now the facts of an experiment are one thing, and the inference which may be drawn from these facts is a very different thing. The facts, if carefully observed, are true and are immutable; the *inference* will depend very much on the theory, in the light of which the facts are viewed, and both may be entirely erroneous. A mere inference is of value only so long as no other inference equally justifiable is presented. If the facts warrant a different inference, on a basis equally intelligible, and which also serves to explain the phenomena, such an inference and the basis on which it rests are entitled to a respectful consideration, equally with the former one. Such an inference here presents itself.

It is quite as justifiable to infer that the vital activity of the nerve-trunk was weakened by the concentrated salt solution (or by the induction current), and wanted only an additional wave of paralysis, which the direct galvanic current supplied, to enable the salt solution (or the induction current) to so effectually interrupt the vital nerve action as to set free "the great property of contractility" which is "an inherent endowment of the muscle" (Drs. Todd and Bowman), and to produce a contraction accordingly.

So far as the facts of the experiment are concerned, they prove this inference quite as much as the former one. But this inference receives a confirmation which amounts to positive proof, from the following considerations: 1st, numerous facts show that muscle is most prone to pass into a state of contraction, not when its motor nerves are most "irritable," but when their influence is withdrawn (see Dr. C. B. Radcliffe's proofs of this, "Lectures, etc.," pp. 95–103); 2d, the fact, clearly proved, that the action of the galvanic current is to paralyze the portion of the nerve between the electrodes, is strong presumptive evidence that its more diffused effects along the nerve-trunk are of a similar character, and are paralyzing also. It would, indeed, be absurd to suppose of a purely physical force like electricity that it could produce a paralyzing effect in one portion of a nerve-trunk, and then, by a reversal of its mode of action, stimulate a contiguous portion. Such an opinion regarding a purely physical force is not for a moment to be entertained as a scientific deduction, and if not, then only one conclusion is possible, namely, that the action of the direct galvanic current is to paralyze that portion of a motor nerve-trunk between the electrodes and the muscle: the condition of catelectrotonus not being a condition in which the activity of the nerve is increased, but one in which it is temporarily abolished. (Here is a further barrier to the objection that it is only currents of extraordinary strength which paralyze. In this case the current is one which has been supposed to excite the nerve; and yet, as has just been shown, the facts, properly interpreted, show that its action has been really that of a paralyzer.)

Notwithstanding the inference referred to above, to which this conclusion is opposed, this is no novel doctrine in regard to this current. Thus, "according to Volta, both directions of the current are depressing in their effects" (M. Meyer, p. 57). Prof. Matteucci found that the "*direct* continuous current" not only "diminished the excitability of nerves," but produced in them "a temporary paralysis" ("Braith. Epit.," vol. ii., p. 661). Dr. W. B. Carpenter writes: "The direct current *weakens* and at last *destroys* the excitability of a nerve" ("Hum. Phys.," p. 351). Here "excitability" is only another term for irritability; and it is on the authentic records that "a nerve deprived of its irritability can neither receive impressions nor transmit them," and is accordingly paralyzed for the time being. Thus it is proved, both from the facts of experiment and from the testimony of leading authorities themselves, that *the ordinary direct galvanic current paralyzes the extra-polar portion of a motor nerve-trunk along which its influence extends* in the direction of the muscle.

The inverse current.—It has already been proved that the action of this current, equally with that of the direct current, is to paralyze the portion of the nerve included *within the circuit*—that is, between the electrodes. What we have now to consider is the extra-polar action of this current between the electrodes and the muscle.

Here the P. pole is nearest the muscle, and, as is well known, the extra polar portion of the nerve, between this electrode and the muscle, is said to be in a condition of anelectrotonus, or of *diminished irritability*. The proof of the paralyzing action of the inverse current is direct, and is palpably admitted in the phrase "diminished irritability," which means lowered vital activity, and is a degree of paralysis varying in proportion to the strength of the current. It is true of weak currents as well as of strong ones.

Experiment.—The two batteries are arranged as last indicated, with the induction electrodes in the middle of the nerve-trunk. Through these a sufficient current is sent to cause a contraction of the muscle. The influence of the inverse galvanic current is then made to pass along the nerve, the portion of which passing toward the muscle is in the anelectrotonic state. So long as the current continues, no contraction of the muscle can be produced by the induction current, which before sufficed for that purpose ("Handbook, etc.," p. 389). Hence the inference stated above.

Dr. Moritz Meyer quotes M. Eckhard for the observation that "*the paralyzing effect of the constant current* is more apparent when it is placed between the muscle and the induction battery than between the induction battery and the free end of the nerve" (p. 62)—that is, a reversal of the position of the batteries as indicated above.

Dr. C. B. Radcliffe states of M. Eckhard: "This very able physiologist has ascertained that so long as the inverse galvanic circuit is closed it is impossible to produce contraction of the muscle by pinching, pricking, or otherwise acting on this part of the nerve . . . . which is consequently in a state of suspended irritability" (Ib., p. 75). *This is a state of paralysis*, because "a nerve deprived of its irritability can neither receive impressions nor transmit them" (p. 78).

While some theoretical conclusions of M. Eckhard as to the varying effects of the direction and intensity of currents on the irritability of the nerve have been corrected by Pflüger, the foregoing facts of simple observation remain unchallenged, and are fully borne out by the authentic records of the experiment in the hands of Dr. M. Foster, as well as others.

Thus, here also, both from the facts of experiment and from the evidence of the experimenters, the ordinary *inverse galvanic current is proved to exert a paralyzing action on the motor nerve submitted to its influence.*

INFLUENCE OF CURRENT DIRECTION.

It is proper to remind the reader here, in the words of Drs. Beard and Rockwell, that "in regard

to the differential action of the ascending and descending currents there has been an almost infinite amount of shallow observation and impulsive writing." These authors offer ample evidence that the effects in question are due, *not to current direction*, but to *the physical effects of the poles*, at one of which acids accumulate and alkalies at the other. "The differential effects of the poles can be differentiated in various ways . . . . the differential effects of current direction, if it be not entirely a myth, is, to say the least, undemonstrated" (pp. 115, 265, 266).

STRONG AND WEAK CURRENTS.

Some reader may be disposed to exclaim: "Oh, all this may be true of very powerful currents of electricity which paralyze, but the reverse is true of moderate currents which merely stimulate." Is such an assertion a scientific deduction, and if so, where is the proof?

What would be thought of the philosopher who should assert that the process of combustion going on in our grate is an essentially different process from that taking place in a conflagration which burns our houses? Is it true that the addition of any number of sparks to the battery spark alters its character, and modifies—nay, even reverses its mode of action? If this is too absurd for serious thought, then just as the lightning flash is inimical to life, so also is the battery spark, in proportion to its power. The difference is one of degree, not of character or quality. As representing differences in the power of action of the same physical force, there is a physical necessity that both shall tend to the same goal. Given a sufficient aggregation of battery sparks and the goal is reached. If the single spark does not reach it, this is not due to any change or reversal in its mode of action, but simply to its lack of power and to the counteraction of other opposing forces.

But, besides this, the currents of electricity here referred to, are in general of the most moderate strength; such, in fact, as ordinarily excite a simple muscular contraction, or, when used for medical purposes, as "benumb" a painful nerve. Those very currents here shown to be paralyzing are the precise counterpart of the currents which have been held to "excite" nervous action and to increase nerve "irritability." Both on this ground, therefore, as well as on the former, the popular notion that weak currents stimulate, while only strong currents paralyze, falls to the ground as unscientific and untenable.

THE INTERRUPTED CURRENT.

When Matteucci found that an interrupted current tetanized a muscle, while the constant current produced a simply negative or passive state of the muscle (owing to the conductivity of its nerve being arrested), and regarding these states of paralysis and tetanus as opposite conditions, he naturally enough concluded that, since the two currents produced antagonistic conditions, they must themselves be opposites in their mode of action.

There was here a double fallacy. The most persistent contracture of muscles is found associated with the most profound paralysis of nerve, a fact which shows them to be not opposite conditions, but in reality different degrees or stages of the same pathological condition: the paralysis representing the separation of the muscle from the influence of the nervous centres; the tetanus representing the divorce of the muscle from nerve-restraint, exercised through and by the motor nerve-trunks and their end-plates and terminal branches. The production of conditions so closely related, by the two phases of the electric current, argues for their similarity rather than otherwise; and this, indeed, is very generally conceded now by electricians. The interrupted current also produces "anesthesia," and its "benumbing effects" are equally on the authentic records. It would be tedious and unnecessary here to detail in how many respects they agree; and it may suffice to quote the opinion of Drs. Beard and Rockwell, that "the essential distinction" in their effects "on the body is mainly of degree." Just as "light is light, be its waves longer or shorter, ... so electricity is electricity, however generated, or however modified by the medium through which it moves" (p. 297, etc.). It would be folly to doubt or deny that the same general character—be it stimulating or paralyzing—which attaches to the galvanic current, attaches also to the faradic or interrupted current; and as the former has been proved to be a paralyzing agent, the same quality of general action must also be attributed to the latter.

I would gladly end here; but justice to this subject requires a brief reference to a singular inaccuracy still perpetuated in our text-books, in the experiment known as that of the rheoscopic frog.

THE RHEOSCOPIC FROG.

Every one is familiar with the interesting experiment in which two frog's legs are prepared by denuding them of skin, and leaving a portion of their chief nerve-trunk attached. If the nerve of one of these, B, be laid across either the nerve or muscle of the other, A, and if near the central end of the nerve A, an induction current be applied, a contraction is produced in the muscles of both: the wave, or impulse, which produces the secondary contraction in B, being transferred from the nerve or muscle of A, with which the nerve B is simply in contact.

Dr. M. Foster (following M. Becquerel) explains that the secondary contraction in B "can only be due to the electrotonically increased natural [electrical] nerve-current in A, acting as a stimulus to the nerve B, when the [natural electrical] circuit is closed by a portion of B, and so causing a nervous impulse, just as the closing of any other galvanic current would" ("Handbook Phys. Lab.," p. 395).

Since this explanation was first offered, the elaborate experiments of Prof. Trowbridge, of Harvard College, have thrown the utmost discredit on the supposed natural currents of electricity in nerve and muscle. It has in fact been conclusively shown that in the previous experiments the electric currents which the galvanometer indicated, originated, not in the nerves and muscles experimented on, but in the extraneous appliances of the apparatus employed. Consequently, this part of the explanation, if not entirely fallacious, can at least be no longer regarded as resting on any substantial basis.

The other part of the explanation, in which the electrotonic state of the nerve is referred to, is manifestly erroneous. Dr. M. Foster's directions are to use an "induction coil" and "the interrupted current" at the central end of the nerve A. Now the induction current does not produce electrotonus, this being a condition of chemical action which attaches only to the galvanic current. That the effect produced is not due to the electrotonic state is further shown by the fact mentioned by Matteucci, that pinching or otherwise injuring the nerve A will also cause the desired contraction. Pinching a nerve, of course, could not produce electrotonus.

This is a fair example of the slipshod style in which many conclusions are arrived at, and handed on from one author to another in the records of physiological experimentation.

It is quite evident that the contraction of the muscles of either nerve cannot be due to the *direct* influence of the battery current, because this current actually traverses no more of the nerve-trunk of A than is within the circuit—that is, between the electrodes; and also because ligaturing either nerve-trunk prevents a contraction of its muscle. A ligature would not prevent the electric current from passing, but it would arrest a nervous impulse. Whatever is done to the nerve by the battery current, or by the pinch, burn, etc., is of a character to modify the nervous impulse; and as electricity has been shown to be a paralyzing agent to nerve-tissue, it is fair to conclude that the impulse is a paralyzing one, and momentarily sets the muscle free to contract. Thus, there is nothing at all in this very interesting experiment antagonistic to the theory which so many facts combine to support, since a paralyzing impulse may as readily pass from A to B as a stimulating one. That electricity is here present in these moist tissues, is very probable. The denuded muscles continue to respire—that is, they absorb oxygen and give off carbonic acid (Prof. Kuss). Here are all the conditions for chemical change, and wherever chemical action takes place electricity is developed. But whoever asserts that this agent has anything to do with the life-work of nerve and muscle will have to enter *de novo* on the task of experimentation in order to prove his thesis.

CONCLUSION.

Around this great central fact of the paralyzing character of electricity all the minor facts of electrical experimentation will be found to arrange themselves in perfect harmony. There is no space here to refer to these, but some of them have been alluded to in former papers, and the reader can readily supply the omission.

Is there any valid ground on which to challenge the conclusions here drawn? I know of none. The plain facts of simple and uncomplicated experiments have been allowed to tell their own story in a natural and straightforward manner. There has been no suppression, concealment, evasion, or false induction. Indeed, for the latter, the simple character of the experiments affords but little scope. The experiments themselves are of undoubted repute, and have passed into universal acceptance.

Nor is the conclusion here arrived at either novel or unheard of. It has been cropping out in the writings of every experimenter during the hundred years which have elapsed since Galvani made his first discovery. Volta, Valentine, Matteucci, Eckhard, and many others whose names are less familiar, had proof of it. Even Dr. Moritz Meyer qnotes "Dr. Brown-Séquard's experiments on the enervating effects of the electric current."

This great truth has been crying out for recognition during a hundred years, but the cry has been ignored, and the penalty is being paid for that neglect. In the absence of the light which this truth would have thrown on physiological experimentation, medical scientists have been driven to *invent* an entirely imaginary system of nervous centres and nerves wholly unknown to the anatomist, to "inhibit" the functions of nerves known to exist, in their attempts to explain the phenomena of the organism. And even then without success. As each new difficulty presents itself, new hypothetical centres or nerves are invoked (among the latest being "a sweat centre," provisionally located in the spinal cord), till the huge and complicated system threatens to be ruined by its very complexity and unwieldiness.

Perhaps no branch of the medical art has suffered more in this way than therapentics, and this result is in great part due to erroneous conclusions regarding physiological inquiry directly due to the suppression of this truth.

Will it be recognized now? That were too much to expect, for reasons which it is needless to enumerate. All great truths have had their periods of suppression, of denunciation, and then of recognition. Doubtless this one will furnish no exception to the rule.

THREE GALL-STONES

REMOVED FROM THE GALL-BLADDER THROUGH THE WALLS OF THE ABDOMEN.

BY CHAS. WM. CALHOUN, A.M., M.D.,

TRIPOLI, SYRIA, TURKEY IN ASIA.

HANNIE MAKROMALIE, aged twenty-one years, married at fourteen years of age. Has two children. Menses regular. Bowels in excellent condition. Appetite always good, and in every way the picture of health. She presented herself July 9, 1880, with the following history: Two years and nine months ago she had a paroxysm of intense pain in the "belly," extending over the right side, and lasting one hour. It "broke her back." The pain passed off of itself, leaving her weak, pale, and sweating. This paroxysm was preceded by light pain in "flashes" for six or seven days. She has never had any icteric hue, diarrhœa, or clayey stools, either then, before, or since, and the color of her urine has always been normal. Jnst one year after the first attack she had another similar to it, followed in three months by a third. She tried various measures to remove the pain, but said "it did not go away till it got ready to leave." With the third attack she was frightened to find a "lump" the size of "a child's head" "inside of her," which remained this size for six months without causing any inconvenience. She did all her housework herself. This "lump" was just below the free border of the ribs on the right side.

At this time (the end of the six months) the tumor began to get red, and felt heavy and hot. She therefore poulticed it, and awoke one morning to find it had opened during the night while she slept. She felt relieved. There were four or five pin-hole openings, all contained within a circle having a diameter of one inch. They all closed except the central one. The discharge was not yellow (bile suspected), did not smell bad (pus suspected), but was "like the white of an egg," and about four ounces in quantity. It has been open one year, during which period the tumor has decreased in size, and she has had but one attack of "that pain" since. The discharge has been constant, somewhat profnse, and as clear as "sugar and water."

She showed me a fistulous opening in the abdominal walls, surrounded by a slight blush, and located in the right lumbar region, 4¾ inches from the umbilicus, 2½ inches below the free border of the ribs, and 5 inches from the right anterior superior spinous

process of the ilium. A tumor the size of a fist could be grasped through the abdominal walls with difficulty, owing to their thickness. The sinus admitted the probe only to a distance of 1½ inch, the diameter being only sufficient to admit the probe. I dilated the sinus, and the next day the probe entered to the distance of four inches. I thought I felt a stone, but did not succeed in finding it again. In one of my post-mortems I found the cystic duct occluded and the gall-bladder distended with a stone, surrounded by clear mucus. Remembering this made me almost sure that this sinus led to a stone. I continued to dilate, but it was not till July 19th that I was positive of a gall-stone under my probe, when my friend Dr. Mareeya fully confirmed my diagnosis. The next day I operated, assisted by Dr. Mareeya. I introduced a probe-pointed bistoury and carefully enlarged the sinus, cutting upward and inward through the inflammatory induration till I could introduce my index finger. I found a constricting ring about three inches from the surface of the abdominal walls, which I divided, and entered a chamber containing only mucus (and blood from the operation). This chamber extended downward about 1½ inch. I then felt in the opposite wall of the chamber a small opening or constricting ring, which I enlarged with a hernia knife, and on introducing my finger found the stones in the gall-bladder, which seemed to be drawn downward and to the right, so that my finger entered it near the fundus and at an obtuse angle with its long axis. I removed, with uterine-dressing forceps, two stones 4½ inches from the surface of the abdominal walls. The stones together weighed thirty-one grains, and, on analysis, proved to be composed of cholesterine and a very small amount of bile-pigment. I introduced a large drainage-tube, gave the patient quin. sulph., gr. x., morph. sulph., gr. ¼.

July 21st.—Patient slept well. Found the tube protruding, and on carefully probing found a stone presenting three inches from the surface of the abdomen. I readily removed it with the uterine forceps, causing only slight pain. It weighed 13½ gr., and was precisely like the other two. I used the forceps as a searcher, but found nothing more. The forceps went in about six inches. My delight at removing two stones at the time of the operation was the reason, probably, that I did not make thorough enough search, and so remove the third at the same time with the other two. 3 P.M.—Temperature, 102¼ F., but she seems very comfortable. Ordered quin. sulph., gr. x., morph. sulph., gr. ¼.

July 22d.—Slept well; eats well; very comfortable.

July 31st.—Came to my office to have the wound washed. The only dressing is a one in twenty solution of carbolic acid. The wound has closed rapidly.

August 30th.—The patient feels she must go home, a distance of four or five days' journey, though there is still a slight discharge of clear mucus, and the fistula, though very small, has not closed. The discharge is so much less than formerly that she is satisfied with the result of the operation.

November 1, 1880.—I am told by her friends that the fistula has closed, but shall not feel sure till I see the patient myself.

The interesting features of this case seem to be the entire absence of any icterus, any clayey stools, any discoloration of urine, any pus during any portion of the entire period, and the youth of the patient.

A CASE OF

DISLOCATION OF THE HUMERUS, WITH MULTIPLE FRACTURE OF THE SCAPULA, WITH REMARKS.

By WILLIAM E. BRANDT, A.M., M.D.,

LATE A. A. SURGEON, U.S.A., HANOVER, INDIANA.

On the night of the 20th of last October, I was summoned to the country to attend a young man, J. S., aged twenty years, who had fallen a distance of fifty feet from a tree while coon-hunting. I learned from the messenger that the patient was rendered insensible by the concussion, and that he remained unconscious for a quarter of an hour or more. After regaining consciousness he had considerable hemorrhage from the lungs or throat. I reached him three hours after the accident, and found him suffering severely from shock. The right shoulder was enormously swollen and contused, he having fallen upon the anterior portion of the head of the humerus and sustained a subcoracoid luxation. Owing to the excessive tumefaction that had taken place, it was with some difficulty that I was able to diagnosticate the rare complication which existed; that is, fracture of the acromion process and fracture of the spine of the scapula, the line of fracture being downward through the body of the bone,* splitting the scapula almost into two nearly equal halves. Having the broken scapula well supported by assistants, I with some difficulty, not having an anæsthetic with me, with my heel in his axilla,† reduced the dislocation. I then, with the aid of compresses and a large roller-bandage, secured the fractured bones in as perfect apposition as was possible, bound the arm and forearm to the anterior part of the chest, and supported them in a broad sling. Ordered morphia sulph. to quiet pain and secure rest. Next day, on my return, found patient still suffering from shock, and unable to sit up to have dressings readjusted without syncope. He had, during this and the succeeding day, several attacks of hæmoptysis, probably due to congestion of the lungs. I ordered morphia sulph. and stimulants, and purgative at night. In a few days I omitted the opiate, gave him generous diet, kept him in bed a week or more, and as soon as the inflammation began to subside I instituted gentle friction and passive motion of the scapulo-humeral joint—fearing, if I waited as long as some of our authorities direct, I would have false anchylosis, and the subsequent history of the case proves that I was right in thus departing from the usual method of waiting a month or more before beginning passive motion, and that I gave my patient the best chance for a useful arm. For within one month's time of the receipt of the injury he could move his arm in nearly all directions, and in six weeks had all the overhead movements nearly as perfect as in the sound arm. Of course there is some flattening in the deltoid region and slight deformity of the scapula, and a tense condition of some of the muscles of the axillary space, which does not cause him any pain or discomfort. This latter condition can only be felt when the arm is moved in certain directions, and I think it will disappear by exercise and massage, and when complete osseous union takes place.

Remarks.—I trust that the following desultory thoughts and fragmentary jottings will not be con-

* See Gross' Surg., vol. i., p. 960, fifth edition, for a similar case.

† See Hippocrates on Articulations, p. 571, vol. ii. Sydenham Society, Adams' edition, London, 1849.

sidered irrelevant, taken in connection with the above case. Dislocations, complicated with fractures in the vicinage of the shoulder-joint, are confessedly among the most difficult to diagnosticate that ordinarily come under the observation of the surgeon. This fact is clearly stated by Gross, Hamilton, Ashhurst, and Erichsen, and other authorities. Dupuytren says that all solutions of continuity of bones in the vicinity of joints give rise to numerous errors of diagnosis; and the remark applies with peculiar force to injuries which occur about the scapulo-humeral articulation. Doubtless every surgeon of a few years' experience can recall to memory cases of injury of the shoulder which taxed his greatest skill in determining the exact nature of the accident.

Sir Astley Cooper, in his classic work on Dislocations and Fractures of the Joints,* in the chapter on Fractures of the Shoulder-Joint liable to be Mistaken for Dislocations, treats of fracture of the acromion and fracture of the neck of the scapula, by which he means fracture through the narrow part of the bone, immediately opposite the notch of the superior costa. Of this latter accident he gives three cases, and he states its diagnostic marks to be three: first, the facility with which the parts are replaced; secondly, the immediate fall of the head of the bone in the axilla, when the extension is removed; and thirdly, the crepitus which is felt at the extremity of the coracoid process of the scapula, when the arm is rotated. The mode of discovering the crepitus is stated to be, for the surgeon's hand to be placed over the top of the shoulder, and the point of the fore-finger to be rested on the coracoid process of the scapula. When the arm is rotated the crepitus is then distinctly perceived, because the coracoid process, being attached to the glenoid cavity, and being broken off with it, although itself uninjured, the crepitus is communicated through the medium of that process. This theory of Sir Astley Cooper on the differential diagnosis of fracture of the neck of the scapula is criticised by Malgaigne,† who declares his disbelief in the statement that the glenoid cavity can so easily fall into the axilla, the coracoid process being suspended to the clavicle and to the acromion by ligaments of such great solidity; and if it did, an infinitely more certain sign would be had in the movements of elevation and depression alternatively communicated to the coracoid apophysis, without omitting the projection in the axilla of the angular sharp, or at least irregular inferior fragment, and which would be readily distinguished from the head of the humerus. As to the very insufficient signs of Sir Astley Cooper, he continues, they appear to me to correspond better with luxation downward with fracture of the glenoid cavity than with any other lesion."

Dr. M. Schüller, of Greifswald, contributes a paper‡ on "Rules for Diagnosis between Fracture and Dislocations at the Shoulder," which, on account of its value, I will quote *in extenso*. In the first place he alludes to the difficulty occasionally experienced by surgeons in the differential diagnosis between fracture of neck of the humerus, in which the lower fragment, the shaft of the bone, is displaced inward and into the axilla, while the upper fragment, the head of the bone, remains in the glenoid cavity.§ In this form of injury, which usually consists in fracture of the surgical neck of the humerus, the long axis of the arm runs obliquely inward toward the coracoid process, the elbow stands away from the side of the trunk, and the deltoid muscle is flattened, or even concave on its outer surface—all signs of forward dislocation of the head of the bone. In many instances a fracture may be readily diagnosticated, partially through crepitation, partially from a determination of the characteristic form of the end of the lower fragment, and of the presence of the upper fragment just below the acromion. Occasionally, however, a precise diagnosis of this injury may be rendered impossible through much effusion of blood, absence of crepitation, and the small dimensions of the upper fragment. Attempts at reduction performed again and again are in such a case always followed by an immediate return of the abnormal condition of the shoulder. Sometimes it happens that in one of these attempts at reduction the surgeon is able to make out crepitus, and then assumes that he has himself produced the fracture through the application of too much force. The author holds that, under ordinary conditions, it is impossible to produce fracture of the neck of the humerus in an attempt to reduce a dislocation at the shoulder. It often happens, however, that in a case of old fracture of the neck of the humerus, mistaken for, and treated as, a case of subcoracoid dislocation, the fragments are again separated in an attempt at reduction. The author does not altogether disapprove of the administration of chloroform in cases of doubt, but holds that, apart from the fact that there may be cases in which the doubt cannot thus be cleared up, it would be more desirable to have some means of making the diagnosis surely and safely without anæsthesia. The method suggested, as very simple and ready in its application, is that of measuring the injured extremity, and especially the distance between the acromion and the point of the epicondyle. In every case of fracture of the neck of the humerus this distance is shorter on the injured than on the sound side, and this shortening is greatest in those cases which most resemble subcoracoid dislocation of the head of the bone. In this latter injury the distance between the above-mentioned anatomical points is increased. The author does not agree with Malgaigne,* who held that this increase in the length of the arm is not constantly met with in cases of dislocation. There is no difference of opinion, however, as to shortening in every case of fracture of the neck of the humerus, with displacement of the shaft inward. Shortening, which in this injury is usually considerable, is, as was acknowledged by Malgaigne, never met with in cases of dislocation. The author, when measuring the distance between the acromion and the external epicondyle, takes care that the arm is abducted, and the forearm flexed at a right angle. The round extremity, when measured, is placed in a similar position. The tape is then carried to the external condyle from the same point of the acromion on each side, and from either its anterior or posterior angle. The words of the celebrated secretary of the Royal Academy of Surgery, Louis, prefixed by Smith to his valuable memoir on the diagnosis and pathology of fractures of the neck of the femur, cannot be held too much in remembrance, and are apropos: "Among all the parts of the art of surgery the science of diagnosis holds the first rank, and it is

* Loc. cit.

the most useful and the most difficult of them all. Without an exact and precise diagnosis theory is almost always faulty and practice often incorrect." I well remember, though a decade has elapsed, that my old surgical master, Dr. David W. Yandell, of Kentucky, the most accomplished *clinicien* I ever listened to, used to dwell with great eloquence and force upon the importance of *accurate anatomical knowledge*, as the only sure foundation for *correct surgical diagnosis*.

Sir Astley Cooper, in his monumental work,* has well said: "A considerable share of anatomical knowledge is required to detect the nature of these accidents, as well as to suggest the proper means of reduction, and it is much to be lamented that students neglect to inform themselves sufficiently of the structure of the joints. They often dissect the muscles of a limb with great neatness and minuteness, and then throw it away without any examination of the ligaments, cartilages, or ends of the bones; a knowledge of which, in a surgical point of view, is of infinitely greater importance; and from such negligence arise the errors into which those novices fall when they embark in the practice of their profession, for the dislocations of the hip, the elbow, and the shoulder are scarcely to be detected but by those who possess accurate anatomical information. It is, therefore, proper that the form of the extremities of the bones, their mode of articulation, the ligaments by which they are connected, and the direction in which their most powerful muscles act, should be well understood.' *Verbum sat sapienti.*

THE CHANCROID—WHAT SHALL WE DO WITH IT?

By C. A. BRYCE, M.D.,

EDITOR OF SOUTHERN CLINIC, RICHMOND, VA.

Of late years the term chancroid has been used to designate a venereal sore, which by many very prominent members of the profession is regarded as a simple sore, the result of impure sexual congress—but non-syphilitic in character and never followed by constitutional contamination.

The treatment of this affection will therefore depend upon the individual views of the prescriber: if we regard it as a non-syphilitic lesion, our remedies will be directed simply to the healing of a sore upon the genitals and the prevention of its local ravages; if, on the other hand, we regard this chancroid as a peculiar manifestation of syphilis, which is often followed by the very worst constitutional disturbances, we will treat the trouble promptly as we would early syphilis, with a view of preventing constitutional contamination. Failing, therefore, to recognize any difference whatever between *chancroid* and *soft chancre*, either physically or in their remote effects upon the system, we are led to regard chancroid or soft chancre as the local manifestation of genuine initial syphilis as much as we do the Hunterian chancre. This belief, founded upon quite an extensive clinical study of these affections, is our excuse for offering a few suggestions in regard to the treatment of chancroid?

Now, in support of the views which we hold in reference to the syphilitic character of chancroid, we would invite the attention of our readers to the following observations:

1. A very respectable portion of the profession will be able to recall a number of cases of chancroid in their practice *followed by constitutional syphilis*; and the number of cases of this kind is entirely too large to explain upon the ground of accidental inoculation. I can now remember a number of such cases in my own practice in which this lesion was not only followed by syphilis of a general character, but also in which (in two cases) the disease was given to the wives of the parties, and they had first *soft chancres*, and afterward constitutional syphilis!

2. The advocates of the non-syphilitic character of chancroid lay peculiar stress upon the fact that it is seldom or never followed by general infection. We admit that it is followed by general contamination *less frequently* than chancre of the indurated variety, and the explanation of this fact is satisfactory to our minds, for we know that the absorbing power of the tissue is lessened, and in many cases entirely destroyed by a high grade of inflammation. This is familiar to every physician. We know that the little operation of vaccination is often rendered inert by the local inflammation at the seat of puncture—the bite of a rabid dog may be neutralized by the prompt onset of inflammation after the use of the actual cautery—and the local severity of the inflammation and rapid destruction of tissue in chancroid is a safeguard in many instances against further trouble.

The difference in the *period of incubation* of chancroid and chancre is regarded by those who deny the syphilitic character of chancroid, as a point of diagnostic value. We think it strengthens our position, for we regard this as an evidence of the extreme violence of the syphilitic poison—it does not wait, but locally destroys the tissues at once, and, as we have said before, thus in many instances protects the system from further damage.

3. Again, we find chancroid occurring much oftener among negroes and filthy whites than among the better class of whites who pay attention to the cleanliness of their persons, and live in better hygienic conditions, thus showing us that we may expect it oftener where filth and other depressing agencies would have a tendency to increase the virulence of the secretions.

As the tendency of the present is to regard chancroid as a benign affection and non-syphilitic, and as our convictions and experience clearly impel us to the belief that chancroid is *genuine initial syphilis*, we feel it our duty to enter a protest against the neglect of specific treatment in this form of syphilis—and would urge our professional brethren to look well to this questionable lesion, which has already been too negligently treated by the profession of late.

* Loc. cit., p. 26, 6th London edition, 1832.

Dr. Levin Smith Joynes, LL.D., one of the most prominent physicians of Virginia, died in Richmond yesterday at the age of sixty-two years. He graduated as A.B. from Washington College, Pennsylvania, and pursued his medical studies at the University of Virginia and the University of Pennsylvania, graduating as M.D. at the former, and subsequently spent two years in continuance of his medical studies in Paris, Dublin, etc. He became Professor of Physiology and Legal Medicine in the Franklin Medical College of Philadelphia in 1846, returning to Virginia in 1849, and continued in practice until 1855, when he was elected Professor of Institutes of Medicine and Medical Jurisprudence in the Medical College of Richmond, with which institution he was connected in various high positions until his death. He became a member of the American Medical Association in 1847, and of its judicial council in 1873.

A CASE OF

COMPLETE AND PROLONGED LOSS OF THE SENSES OF BOTH TASTE AND SMELL.

RAPID RECOVERY UNDER THE INFLUENCE OF GALVANISM.

BY A. D. ROCKWELL, M.D.,

ELECTRO-THERAPEUTIST TO THE NEW YORK STATE WOMAN'S HOSPITAL.

IT is within the experience of all of us that the sick not unfrequently promise blessings in case of recovery; if, however, our therapeutics prove futile, they are on the other hand too often ready to do the other thing. Happy then, is the man who, instead of a curse can command a blessing, and thrice happy he who has aided in a recovery, the conditions of which are such that he is blessed three times a day. Those unfortunates who simply "eat to live," might not perhaps be so appreciative as the patient whose case is here given, and who sent word that she blessed me three times a day; but the wise and happy who combine both purposes, and, like the hero in Charles Lamb's essay "On the Origin of Roast Pig," "live to eat" as well, could hardly fail to be equally grateful. The literature of the neuroses of the nerves of special sense is not very extensive, but anosmia, or loss of the sense of smell, is not unfrequently met with.

I have seen quite a number of such cases of a chronic character, and have reported a number of recoveries. Complete loss of the sense of taste, however, is very rare, and in ten years I have met with but two such cases, the first of which occurred in a patient sent to me by Dr. A. N. Brockway. Permanent recovery followed treatment.*

The second case was a young lady from Wilton, Conn., who came to me January 12, 1880, through Dr. W. W. Rodman, of New Haven, Conn. The sense of taste had been so completely lost for ten months that it was the same to her whether she partook of what was most bitter and disagreeable, or of the most attractive and delicately flavored dishes. In January 1879, the patient suffered from a sudden and severe attack of influenza, followed by fever. In March a second attack came on, resulting not only in a loss of the sense of taste, but in a loss of the sense of smell also. It was evident that all the gustatory fibres were involved, for, however completely the various portions of the tongue and surrounding mucous surfaces were tested, it was impossible to elicit the slightest suggestion of the existence of this special function. To the influence of the galvanic current, the vital function of the nerve responded but faintly, so faintly, indeed, that it was hardly recognizable to the sense of the patient. After two or three applications, however, the metallic taste was very quickly and distinctly appreciated, and in about two weeks the lost function was quite restored and still remains normally acute, after a lapse of nearly a year.

A NEW MEDICAL COLLEGE IN PHILADELPHIA.—It is stated that there will soon be organized a new medical college in Philadelphia, under the charge of members of the regular profession. A charter of one of the colleges existing before the war has been resurrected, and a location near Broad and Market streets selected for the new institution.

* The case is detailed in Beard and Rockwell's Med. and Surg. Electricity, p. 684.

EXTREME OPISTHOTONOS IN A CASE OF HYSTERO-EPILEPSY.

BY J. SOLIS COHEN, M.D.,

PHILADELPHIA, PA.

AN hysteric girl, eighteen years of age, of German parentage, has been under my care, in hospital service, for the past three months, with some unusual features of this disease. She has had continuous tremors of the left hand and arm for more than a year, with marked anæsthesia of certain portions of that limb. Some five months ago, while swinging to the utmost extent of the apparatus now in common use at fairs and picnics, she was taken with her first epileptic seizure; since which she has been subject to repetitions at irregular intervals of from a few days to a fortnight, when under the influence of large doses (120 grains per diem) of one of the bromides, and as frequently as every day, when she is allowed to recover, at intervals, from their influence. (It may be parenthetically mentioned, that the use of cod-liver oil in association with the bromide, has, for weeks together, prevented any objective indications of hyperbromidism.) A strong induction current to the limbs, pressure upon the ovary, and other similar expedients, will immediately stop any one paroxysm, of a series, through which she is passing; but the effect is only momentary. There is also in this case some susceptibility to the influence of certain metals placed upon anæsthetic portions of the skin. These spots are no longer confined to the tremulous limb, but exist along the entire side. For proper study and presentation, this case has been brought by me to the notice of a professional friend deeply interested in studies of the nervous system; and the chief object of this communication is to record the extent of the opisthotonos, which occurs during the epileptoid seizures.

As soon as the patient rests upon her heels and occiput, as in usual extreme examples, the head continues to rotate slowly backward until the occiput rests upon the dorsal vertebræ; and the patient then *remains supported by her face and her heels.*

The paroxysm can be induced at will, by pressure on the sensitive cervical regions, or upon certain hyperæsthetic spots in the temporal and parietal regions. The general nutrition of the patient is excellent. She can sew well with the tremulous hand, and complains only of extreme muscular fatigue after her paroxysms.

LOCATION OF THE VASO-DILATOR NERVES.—MM. Dastra and Morat announce that they have discovered in the great sympathetic in the dog the vaso-dilator nerves, which have been long sought in the cerebro-spinal nerves, viz., the dilators of the ear in the dog, rabbit, and goat; the cutaneous dilators of the upper and lower limbs and the buccal dilators.

LITHOLAPAXY IN GERMANY.—The operation of litholapaxy by Bigelow's method has been the subject of extended debate among the surgeons of Vienna. Billroth reported six cases in which he had employed the method, each time with success. Dittel related twelve successful cases. All the other surgeons who took part in the debate, and who had had personal experience in the operation, spoke in its favor. It may be asserted that litholapaxy has become an accepted part of surgical practice in Vienna.—*Chicago Med. Rev.*

Progress of Medical Science.

Argyria Following the Frequent Pharyngeal Application of Nitrate of Silver.—A woman, aged forty-six years, noticed a bluish discoloration of the entire cutaneous surface, following repeated pharyngeal cauterizations with the silver nitrate stick. Similar cases have been recorded, one by Krishaber, and a second in the *Gazetta medica Italiana* (1862). The absorption of the silver salt takes place in part from the mucous surface of the cauterized portion, but principally from the intestinal surface, the products of cauterization being conveyed to the alimentary canal.—*Archives méd. Belges*, September, 1880.

The Resuscitation of Animals Subjected to Intense Cold.—It has been generally assumed that the safest method of revivifying apparently frozen bodies was to subject them to a very gradual elevation of temperature. The experiments of Beck, Horwat, and Jacoby, however, seemed to show that the speedy application of considerable heat was more beneficial. In order to determine the truth of the matter, Lapschinski (*Centralbl. für Chir.*, No. 15, 1880) instituted a series of experiments upon dogs, the results of which have led him to present the following conclusions: 1. The quickest way to resuscitate dogs which have been submitted to the influence of severe cold (the effects of which were measured by a thermometer placed in the rectum) is to rapidly produce an elevation of their temperature. This is most readily accomplished by plunging them into a hot bath.

2. Even in cases of intense congelation, where the method of gradual heating fails to revivify, a hot bath will have a life-saving effect.

3. When partially frozen dogs are rapidly warmed by being plunged into a hot bath, their subsequent febrile manifestations show a less degree of intensity than when the animals are gradually heated.

4. An examination of the blood of the animals subjected to cold, showed the corpuscular elements to have assumed polymorphous shapes. Many red blood-globules had also become colorless, and frequently the plasma had assumed a yellowish red tint. The latter appearance evidently resulted from the loss in hæmoglobin of the blood-disks. When blood was taken from the dogs during the process of resuscitation by heat, these conditions of the blood were less marked. Animals which died in spite of the use of the hot bath, showed, in many cases, no morbid alterations of the blood.

5. The muscles were found changed only in the more superficial parts, where the action of the cold had been most intense. Thus, certain opacities were discovered, some fibrillæ had lost their transverse striation, and others showed varicose protuberances. When the dogs were gradually warmed, the rectal temperature would continue to sink two to three degrees in spite of chafing, rubbing, etc. The author finally asserts that the action of the hot bath is to restore the vitiated vital functions, and that cardiac activity is stimulated by warm blood.—*Med. Chir. Rundschau*, October, 1880.

Hypodermic Injection of Water for the Relief of the Cough of Phthisis, and other Symptoms.—Prof. Landouzy states (*Le Progrès Médical*, No. 48, 1880) that the distressing cough of phthisis may be effectively relieved by the subcutaneous injection of a syringeful of distilled water. The injection may be made at the neck, near the larynx, in the infraclavicular region, or in an intercostal space, accordingly as the patient points out one or another of these localities as the starting-point of the irritation. It appears to be of some importance to hide the nature of the fluid from the patient's knowledge, and for this reason a few drops of aqua laurocerasi may be added to the water. The author also alludes to the good results obtained by similar procedures in cases of neuralgia, which have been described by Dieulafoy, Potain, and others.—*Allg. med. Cent. Zeit.*, December 8, 1880.

Dr. Raymond Tripier has for several years past employed the same measure in order to stop the vomiting of patients suffering from phthisis. He also adopts this line of treatment in certain cases of dyspeptic vomiting, especially when the patients are nervous women who stand in dread of morphia. The site of injection was always the epigastric region. Cold water appeared to be the most reliable and serviceable.—*Lyon Médical*, December 12, 1880.

The Transmission of Equine Glanders to Rabbits.—At a recent meeting of the *Académie de Médicine*, M. Colin read a paper with the above title which contained an analysis of the virulence of glanders. In his experience the disease might prove fatal without producing any visceral lesion. The inoculations might lead to deep ulcerations. In some instances the experimental inoculation had been followed by the development of pulmonary tuberculosis in the rabbits subjected to the experiment. In other cases no appreciable effects were produced. Glanders did not appear to be a malady with a uniform type of occurrence, nor did the disease always progress toward a definite end. It seemed rather to consist of different morbid elements, which, by successive addition, produced the cumulative effect of the typical and complete affection. An arrest of progressive development might occur at almost any time, thus leaving the disease in an unfinished condition.

Virulence was neither a constant nor yet a necessary element of glanders. The formation of tubercle was not an inherent property belonging to the poison. In conclusion, M. Colin pointed out that in all probability there existed many other diseases which resembled glanders in this respect, viz., that although of common origin and identical in nature, they would appear as distinct maladies in different animal species. For this reason, in seeking to determine the identity of diseases by experimental means, animals should be avoided in whom the disease assumed new or different aspects, or did not reach the ordinary termination.—*Le Progrès Médical*, December 4, 1880.

Inoculation for the Prevention of Carbuncle.—At a meeting of the Paris Academy of Medicine, M. Bouley read a paper on the above subject. He referred to a previous communication of Toussaint, to the effect that the latter had succeeded in producing, by inoculating sheep, the immunity from carbuncle. Renewed investigations had confirmed the truth of these assertions. For purposes of inoculation, carbolized or, otherwise purified serum had been employed. The direct virus of the malignant pustules had not been used. A few of the inoculated animals had died, but the remainder had acquired a subsequent immunity from the disease. At least they survived inoculations with the unchanged virus

taken from recent cases of anthrax. Whether natural infection would kill them remained to be seen.

Chauveau had also found that the young born of animals, which had acquired the disease by inoculation in the latter months of pregnancy, remained invulnerable. Successive inoculations appeared to be indicated, just as human re-vaccination should be universally practised.—*Archives génér. de méd.*, November, 1880.

Æsthesiogenous Properties of Certain Kinds of Wood.—The alleged efficacy of metallotherapy, as demonstrated by Despine, Burg, and Dumontpalier, have led M. Dujardin-Beaumetz to institute a series of experiments with bits of wood. He found that in hysterical patients cutaneous sensibility may be considerably modified by the application of certain kinds of wood. Xylotherapy is the new word which denotes this kind of wooden treatment. The author concludes: 1. That certain kinds of wood possess evident æsthesiogenous powers. 2. Cinchona bark appears to occupy the first place in this connection. Sanderac, rosewood, etc., follow. 3. The wood from other kinds of trees is inert. The poplar, oak-tree, sycamore, etc., belong to the latter group.—*Bull. gén. de thér.* in *Archives méd. belges*, September, 1880.

Severe Disease Caused by Intestinal Parasites.—The long thread-worm (*Trichocephalus dispar*) is generally held to be an essentially harmless parasite, inhabiting principally the cæcum and colon, where its presence causes no morbid symptoms. A case was recently observed by Burchardt (*Deut. med. Wochenschrift*, November 27, 1880), where this parasite became the occasion of serious trouble, producing alarming symptoms and even threatening life. The patient, aged eighteen years, had suffered from worms in his childhood. In April, 1873, without known cause, persistent vomiting came on. Soon diarrhœa developed, and after an apparent temporary improvement, those symptoms returned with increased violence. Constitutional disturbances likewise appeared. Organic lesions could not be made out. At length an examination of the patient's fæces revealed the abundant presence of ova of the tricocephalus. The number of these worms was computed to be very great. Vermifuges, drugs, and other modes of treatment did not effect the desired cure. Partial peritonitis developed, and the patient vomited bloody matter. In June, however, an amelioration of his symptoms took place, the patient daily drinking Carlsbad water. Several months later, a second attack of peritonitis occurred. At this time he also lost his voice, though the aphonia left him a few months afterward. Finally the patient made a good recovery. Although the complete absence of parasites was not positively ascertained, he remained cured. Upon examination, it was found that several persons inhabiting the same house in which the patient had formerly lived, also had similar intestinal worms, but in apparently smaller numbers. These persons showed only very slight symptoms, such as headaches, vertigo, diarrhœa, etc. The aphonia of the case in question was explained as a reflex symptom.

Case of Villous Growth of the Bladder—Removal by Perineal Incision.—At a meeting of the Clinical Society of London, Mr. Davies-Colley reported a case of villous growth of the bladder, and its successful removal by perineal incision. The patient, a young man aged thirty-two years, had suffered from hæmaturia for eight years. When admitted into Guy's Hospital he was fairly nourished but very anæmic. His family history was good. There was a continual desire to micturate, and a feeling as if something always remained behind in the bladder. Blood was passed, sometimes at the beginning, sometimes at the end of micturition. No stone could be detected, and all efforts to find villous masses in the urine failed. No tumor could be felt per rectum. The operation for lateral lithotomy was then performed, and upon examination, a slight projection was discovered on the left side of the fundus, and a cord-like process running from it; to this was attached a soft pinkish white tuft of villi, which was removed with the forceps. No other growth could be felt. There was but little hemorrhage during the operation. The patient made a rapid recovery, and in two weeks the urine ceased to flow from the perineum. Two months after the operation there had been no return of the hemorrhage; the irritability of the bladder had ceased, and he was in the enjoyment of perfect health. The tumor grew from the posterior wall of the bladder, at a point about three inches from its neck, and one inch to the left of the middle line. It consisted of a fibrous stalk one-sixth of an inch thick and two inches long, terminated by branching filaments from half an inch to three-quarters of an inch long. These filaments contained capillary loops, invested by many layers of epithelium of a cylindrical type.—*Med. Press and Circular*, December 15, 1880.

Case of Cholecystotomy.—An interesting case of cholecystotomy, performed for dropsy of the gall-bladder due to impaction of a gall-stone, has been reported in the "Medico-Chirurgical Transactions," vol. lxiii., by Dr. Lawson Tait. The patient was a female who had enjoyed good health until the summer of 1878, when she complained of severe spasmodic pains in the right side, which were aggravated by walking or by lifting even slight weights. In September of that year she noticed a swelling at the seat of pain, and this slowly increased. She then began to lose strength and flesh rapidly, and on admission to the hospital presented an emaciated and almost cachectic appearance. She suffered from incessant headache and obstinate constipation. When examination was made, a heart-shaped tumor was detected at the seat of pain, directly over the right kidney, which was perfectly movable and extremely tender to the touch. No decided diagnosis was made, but in consultation it was determined to open the abdomen, as recommended by Drs. Hanfield Jones and J. Marion Sims, in order to ascertain the nature of the tumor. An opening was therefore made in the abdomen in the middle line, to the extent of four inches, the umbilicus forming the centre of the incision, when it became evident at once that the tumor was a distended gall-bladder. After withdrawing some twelve ounces of a white, starchy-looking fluid, the gall-bladder was opened at the point of puncture, and a large, round gall-stone removed, weighing 4.2 grammes. On further search another of larger size was found, impacted at the entrance of the duct. This was difficult to seize, and was subsequently found adherent to the mucous surface. To remove the impacted stone without tearing the walls to which it was attached was accomplished by a very careful and protracted lithotrity, when the nucleus was discovered and removed. The cavity was then washed out thoroughly, and the wound in the gall-bladder stitched to the upper end of the wound in the abdominal wall by continuous sutures,

leaving the aperture in the bladder quite open. The abdominal opening was then closed in the usual way. The operation was performed with complete antiseptic precautions. The patient rallied subsequently, and continuing to improve, left the hospital in one month, free from pain and all her former symptoms.

Morphia and Chloroform in Producing and Maintaining Surgical Anæsthesia.—Dr. Alexander Crombie has contributed to the *Practitioner* for December, 1880, his experience at the Mistford Hospital, Dacca, Bengal, on the combined use of morphia and chloroform in producing and maintaining surgical anæsthesia. The expedient suggested by Claude Bernard had led the doctor to experiment on the human subject, and from his observations we have deduced the following: the advantages derived from the combination are, first, the prolongation of the anæsthetic effect of the chloroform, once it has been established; and second, the small quantity of chloroform required to keep it up afterward. The first advantage is most conspicuous in operations about the mouth and face. The prolongation of the anæsthesia originally induced in this way is often so great as to enable the surgeon to perform operations of the first magnitude without being interrupted by the necessity of recommencing the inhalation of chloroform on account of the patient returning to consciousness in the middle of it. Vomiting in some cases occurs very early and often before anæsthesia is complete, but in the later stages of an operation, or after removal to the ward, it is very rare indeed. Chloroform-asphyxia, says the doctor, has practically ceased to form part of his experience of the dangers of that anæsthetic. The preparation used is the common liquor morphiæ hydrochloratis freshly prepared. Twenty minims are injected into the cellular tissue of the upper part of the front of the abdomen immediately after the patient has become anæsthetized. The towel or napkin for the administration of chloroform is discarded for a metal cup with a perforated bottom, and with a piece cut out of the side for the reception of the nose. The chloroform is sprinkled on a piece of sponge which occupies the bottom of the cup. The whole fits loosely over the nose, mouth, and chin; so loosely that it is impossible for the most careless administrator to prevent the freest admission of air to the nostrils at each inspiration. As soon as there is complete anæsthesia, the condyle of the lower jaw is pushed forward out of the glenoid cavity on to the eminence in front. If this displacement of the lower jaw forward is properly carried out, there will not be the least stertor or other sound of impeded passage of air to and from the windpipe during the whole continuance of a long operation performed in a condition of the deepest insensibility. If, during the operation, there is the least noise in the breathing, we know that this traction on the root of the tongue is not being efficiently maintained, and a word of warning to the assistant charged with watching the anæsthesia suffices, by directing his attention to it, to restore that free and noiseless respiration, which must be insisted upon throughout operation. Of the other great risk of chloroform—paralysis of the heart—Dr. Crombie has had no experience either before or since he has adopted his present practice. The advantages of chloroform over ether in point of convenience, are so great, that only the admitted greater safety of the latter could have led to the present partial abandonment of chloroform as an anæsthetic in surgical practice. In India, where, ordinarily, they perform operations with a temperature of the air at, or a little below, the boiling-point of ether, they have had no choice.

A Form of Diabetes Associated with Disease of the Pancreas.—In 1877 M. Lancereaux read a note at the *Académie*, in which he demonstrated the existence of a form of diabetes mellitus, found in conjunction with pancreatic lesions. This, he claimed, constituted a special and distinctive variety of diabetes, characterized by a "*début brusque*," considerable emaciation, with polydipsia and polyphagia, by peculiar alvine evacuations, and especially by a very rapid evolution.

The study of Lancereaux has been made the basis of further investigations by M. Depierre, which have led to the discovery of new facts in this connection. Various kinds of pancreatic alterations may be regarded as leading to this kind of diabetes. They may be primary lesions, or they may be the secondary result of the presence of calculi, or else they may be caused by compression of the ducts due to neoplasms. In all such cases there appeared to be a complete abolition of the pancreatic function. This suppression of a digestive function is revealed by special symptoms, thus constituting a variety of diabetes (called by the author "emaciating diabetes") which differs greatly in its clinical aspects from ordinary polyuria. In the latter disease there is said to be, as a rule, an initial stage of obesity, or at least of apparent health, thus rendering the progress of the malady slow and insidious. In pancreatic diabetes, on the other hand, we notice along with the absence of embonpoint a quite sudden explosion of symptoms. These ordinarily consist of grave intestinal manifestations, vertigo, vomiting, and jaundice. True, these symptoms after a while disappear, but they leave the patients in a condition of profound debility. Soon the essential symptoms of the disease put in their appearance. Sometimes, indeed, they occur from the very beginning, without any previous indications of morbid changes. They are polydipsia, polyphagia, polyuria, and autophagia (the latter probably meaning tissue-waste and emaciation). This combination of symptoms is rapidly established, reaching an acme in a few weeks or months, and it is this very point which appears to afford pathognomonic indication of the existence of this variety of diabetes. The habitual presence of diarrhœa is also noted. Sugar is voided in great abundance with the urine. Pulmonary phthisis is also a frequent complication. Emaciation is rapid. In a few months the patients lose successively their physical, intellectual, and genital powers. Then complete prostration and profound marasmus set in, to which there is superadded hectic fever, with the symptoms of consumption. The average duration of the sickness is about twenty months, though it may end in half a year, or last even three years. Greasy or creamy stools may afford a clue to the establishment of the diagnosis of pancreatic diabetes, but it must be remembered that they occur also in other affections of that organ. Another point which must be considered is the deficient digestion of nitrogenized substances in atrophic conditions of the pancreas. Thus, pieces of undigested muscle found in the stools of patients, may awaken a suspicion of this disease. Besides the ordinary treatment of diabetes mellitus, the administration of pancreatine suggests itself as affording a possibility of artificially supplying the lacking aids to digestion.—*Journal de méd. et de Chir. prat.*, December, 1880.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 29, 1881.

SHALL WE CHANGE THE CODE OF ETHICS?

At the next meeting of the Medical Society of the State of New York, to be held the coming week, the recommendation of the Medical Society of the County of New York for a revision of the Code of Ethics will be presented. That the time has come for bringing to an issue the question as to the advisability of such a measure, is admitted, not only by the members of the county society in question, but by many members of the medical profession throughout the country.

The experience of the county society, during the past few years especially, has shown that many sections of the code are susceptible to such liberal construction as to be practically valueless as guides for conduct or as means of discipline. At present it seems to be impossible to draw a line between such as wilfully disobey the law and such as only innocently err. A code which is subject to such varied construction is oppressive only to such as conscientiously strive to follow its letter and spirit, while to others who are otherwise disposed, it is a cloak for unmanly conduct and hypocritical pretension.

The various committees on ethics of the New York County Society have proved time and again that it is almost impossible, under existing circumstances, to secure a conviction of some of the most flagrant offenders against even the letter of the code, simply because such offenders presume upon what they term their high positions in the profession. From what we can learn, this experience has been repeated by committees on ethics, not only of the minor societies, but of many of the larger ones, not omitting the very fountain-head of discipline, the American Medical Association itself. Hence, a belief has gained currency among the profession that the code, as at present constituted, is nothing more than a convenience for the strong, and little else than a means of discipline for the weak.

Any doubts regarding the truth of this statement can be set at rest by a perusal of the able report of the committee of the county society already referred to. The committee endeavored to call the attention of members to violations of the code regarding advertising. Almost without exception, the guilty parties began to make excuse. One prominent offender stated that the profession was safe in his hands, and that he should continue to do as he pleased. In the same connection is a letter from a medical gentleman withdrawing his membership from the society, on the ground that the code is not equal in its application to the larger and smaller men. He very properly does not believe that a man, merely because he may be a professor, has a right to advertise himself any more than a more obscure individual. The committee appear to be unable to reconcile the apparently opposite situations, and wisely ask the society for help in the matter.

We cannot be expected at this time to go into exhaustive detail as to other reasons for revision of our ethical laws. By so doing we would be repeating a very old story. We can only urge the necessity of revision on general considerations. Laws which cannot be respected and enforced are useless. The progress of civilization has made it necessary that laws be modified to suit the times. Many of the conditions that existed during the period when the laws were framed are so changed as to render many of the provisions virtually obsolete, and their enforcement ridiculous. This is due to the fact that the relations of the profession to the public have changed very much during the last few years. The people are better educated than formerly, and better appreciate their wants. The tendency of the age is toward liberality of thought and feeling. The medical profession cannot afford to stand aloof from these influences, and must not trammel itself with inconsistent rules of action, or absurd lines of conduct. Its culture and influence are sufficient to enable it to be thoroughly liberal on all matters relating to the health and welfare of the community. This being the case, the time appears to have arrived when the State Society can take intelligent action in revising its code. Its action in the premises will be viewed with great interest over the country. That body should feel the responsibility thrust upon it, and should be ready and willing to act promptly and efficiently. The matter should be referred to a committee composed of men of large experience, commanding influence, and unquestioned integrity. To such, the task of revision may become a simple affair. Their principal work would consist in pruning. The nearer the code can be made to accord with the golden rule the more perfect will it become. From this standpoint there is room for improvement in all directions, and a great deal can be said in very few words.

THE DOOM OF THE SPRAY.

It cannot be disputed that the results obtained under the Lister method of treating wounds have been at least equal to those secured with other surgical dressings. But while Listerism has led to improved surgical therapy, the intrinsic merits of the method are, perhaps, more than counterbalanced by certain imperfections and disadvantages which cling to its strict enforcement. Its spread and progress, at first slow and fitful, soon assumed astonishing dimensions. For a time opposing voices were drowned in the universal clamor asserting its vast superiority over all other known methods. When a surgeon failed to achieve a brilliant result, when the wound did not promptly and properly heal, the ever-ready excuse was that some precaution had been neglected, some antiseptic detail omitted, in fine, that carelessness or oversight on the part of the surgeon were alone responsible for the mishap.

Such unreasoning acquiescence in the details of a practice, which was based on largely theoretical deductions, was especially noticeable in Germany. There the complicated system became almost a universally accepted religion, and strict orthodoxy was henceforth demanded of its followers. More than this, some enthusiastic Listerites discovered additional details of treatment, so that in Germany, the paraphernalia of the new creed were reinforced by further antiseptic minutiæ. Some who worshipped at this newly erected altar even uttered the proud boast that Lister would soon have to visit Germany in order to study the complete modus operandi of perfected Listerism. Could the unfettered supremacy of such a dogma last? As a matter of fact it has not lasted.

In other countries, while due cognizance was taken of the new departure, the enthusiasm which it kindled in the mind medical lacked the intensity of German feeling. Nevertheless, England may also be said to have accepted the method (not its principles) as the dominant one. This was done rather reluctantly, but none the less universally.

In France, Listerism did not spread with epidemic contagiousness. The French mind, despite its tendency toward enthusiasm, paused before venturing to pronounce a definite conclusion. Nor has the new method won a universal acceptance from the calmly deliberating and practical American surgeon. That antiseptic practices possessed elements of importance, was admitted to have been proven by abundant testimony, and the conjoined experience of hospital and private treatment. But the spirit of impartial investigation was rife within us, and inquiries were directed toward the separation of essential measures from superfluous details. In a previous issue of the RECORD, our own position in the matter was fully explained, and the grounds set forth for an opinion then held. What was at that time expressed as a well-founded conviction, has not been weakened or modified since. On the contrary, it has gained strength from the additional experience of renewed observations and accurate statistics. We found at that time in perfect cleanliness, in complete rest, and in thorough drainage, more important adjuvants of successful wound-treatment, than in the continuously increasing paraphernalia of antiseptic Listerism so-called. Concerning the beneficial action of the spray we were especially sceptical.

It is with some feeling of justifiable gratification, therefore, that we have lately noticed a decided movement of opposition among the heretofore staunch advocates of Listerism. We refer, of course, to the German surgeons. This opposition is directed mainly against the use of the spray. With the roughness characteristic of Teuton energy, when once roused, the facts are demonstrated and conclusions drawn which tend to establish that the use of the spray is of doubtful utility, if not of positive harm.

Three principal articles have issued from the German medical press in very rapid succession, and while in every case the author's aim has been to show that the spray can and should be dispensed with, the ways in which this proof is established vary somewhat and deserve a brief notice. Trendelenburg (*Langenbeck's Archiv*, vol. xxiv.) and v. Bruns (*Berliner klin. Woch.*, No. 43, 1880) present irrefutable statistical data, showing that the spray is, to say the least, a surgical pleonasm when ordinary antiseptic precautions are observed; or perhaps we might say, when rigid cleanliness is enforced. Since the spring of 1879, v. Bruns alone performed one hundred and forty-four severe operations, among the number of which there were sixty-two amputations and twenty-six articular exsections. In not a single instance did a fatal termination mar the gratifying excellency of his surgical successes. The record of Trendelenburg is similarly brilliant. In no case was the spray employed. Certainly its use could not have improved the results, but we may question whether it would not have made them worse.

Mikulicz (*Langenbeck's Archiv*, vol. xxv.) has gone a step farther. Starting with the fact that the alleged germicidal action of the spray must be the result either of chemical or mechanical action, he first shows that, as regards the former, careful irrigation is a better, safer, and more efficient procedure. Then, by direct experimentation, he proves that particles of dust, germs, etc., suspended in the air, are caught in the current of the spray and precipitated in vast numbers upon the exposed surfaces. Such argumentation speaks for itself. Hence, to borrow the title of v. Bruns' article: "Away with the spray!" If, then, the purifying power of the spray becomes a mere untenable assertion, the one essential feature of his method, which has been em-

phasized and insisted upon above all others by Lister and the Listerites, falls to the ground, and with it the principles upon which it is based. Antiseptic surgery, however, will stand the test of time, because antiseptic surgery is but a convenient expression, to denote what we have always regarded the essential factors of successful wound-treatmeut, viz., a scrupulous cleanliness, complete rest, and thorough drainage.

STATE AND NATIONAL MEDICAL LEGISLATION DURING THE SEASON.

TWENTY-FIVE state legislatures began their regular sessions during the present month. As there are a number of measures in medical legislation which ought to be carried out this winter, it behooves the profession not to forget that the opportunities are before them now.

We have already referred to the matters that are likely to come before the legislature at Albany; but measures of much more importance are to be urged in the legislatures of other states.

At the annual meetings of many of the state medical societies, last spring, resolutions were passed and committees appointed looking to the securing of laws creating state health boards or regulating the practice of medicine, and we may expect that in a number of states there will be great efforts to secure the legislation desired.

A specially strong movement is on foot to obtain a law regulating the practice of medicine in Pennsylvania. The medical press of the state has urged the measure, and it will not be creditable to the energy or influence of the profession there if they do not succeed. Bills to secure a similar object were introduced into the legislatures of Massachusetts, Iowa, and Maryland last winter, but they failed. Attempts were also made to improve the medical registration law in Kansas, which is now worse than none at all. These attempts are to be renewed. If the recommendations of state medical societies is any index of what may be expected in legislation, there are a large number of other states where laws, medical and sanitary, will be advocated. The success, up to the present time, of the New York registration law will encourage efforts to extend its application.

In Congress some results of interest to pathology may be expected, if a national cattle commission is created. The appointment of such a commission has been recommended by the Secretary of the Treasury and by a national convention of live-stock owners. It is opposed only, as far as we can learn, by the Commissioner of Agriculture, who believes that his department is competent to take charge of the matter. This commissioner has shown much energy in encouraging the cultivation of sorghum; but the work of his veterinary experts, though praised as better than none, has been crude in character, and, to those most interested, very unsatisfactory. We venture to side with the Secretary of the Treasury and of the *National Live-Stock Journal* in the opinion that a cattle commission ought to be established.

The National Board of Health has, on the whole, justified its existence, and ought to be continued with its present powers. It costs, we believe, somewhat over $100,000 annually. It would gratify that very large part of the profession which is reminded of the board's beneficent existence only by its *Bulletin*, if the pages of that immortal weekly were enlivened with matter of greater sanitary interest and scientific value. With an income of $100,000 something better might be published than the condition of the subsoil in obscure southern districts, or the mortality rate on the North African coast.

A measure that greatly deserves the attention of Congress is that of putting the Marine Hospital Service on a thoroughly non-political basis. A bill for securing this object, by obliging the officers to be appointed by the President and confirmed by the Senate, was introduced and favorably reported upon at the last session of Congress. The bill was not reached in the regular order, however. The Marine Hospital Service does much more medical work than is performed in either the army or navy, and its officers, as professional men, deserve the security and position which a commission would give them. The bill has been so widely indorsed by the medical profession, and is so manifestly just, that we cannot doubt its ultimate passage.

ANOTHER REPORT ON THE ADULTERATIONS OF FOOD.

UNDER instructions from the National Board of Health, Dr. Charles Smart recently undertook an investigation to determine the prevalence of adulteration in food. The results of his work have appeared in a supplement to the *Bulletin of the National Board of Health*. The substances which he examined were tea, coffee, sugar and syrups, flour and bread, cream of tartar and baking-powders, confectionery and spices. Seven hundred and thirteen samples were examined. Of these, three hundred and four were from reliable and four hundred and nine from suspicious sources. Of the former number 7.89 per cent. were adulterated; of the latter number 44.74 per cent. These percentages, however, indicate little, because most of the adulterations were in ground spices, while the more important food-products were quite pure. The investigator states that with such exceptions as alum in bread and baking-materials, sulphate of lime in baking-powder, the debasement of milk by dilution, and the poisonous pigments used in confectionery, the adulterations cannot be considered deleterious. They affect the pocket of the individual rather than his health. If repressive laws are to be enacted, therefore, they must be ad-

vocated, we are told, on commercial and ethical rather than on sanitary grounds.

These conclusions of Dr. Smart are very much like those of other investigators in the same line. The report, indeed, though it shows much industry and judgment, is a somewhat commonplace one. In the investigation of teas and coffees, for example, the same old method of buying samples, examining, analyzing and reporting percentages, is adhered to. A few hours spent among the establishments of New York brokers would astonish the learned gentlemen who make the annual adulteration reports to health boards. The raising low grade teas and coffees to higher grades is a large industry both in this and other cities. An investigation which would show whether the various dyes, clays, bleachings, sweatings, etc., which teas and coffees get during their evolution from low-priced to high-priced articles, might be of some sanitary value as well as scientific interest. The author of the report before us, however, states that he did all that was possible in the time allotted to him; he cannot, therefore, be blamed for deficiencies. This is the third report from the National Board of Health, which has only ordinary, or less than ordinary, merits. It would be well for an organization that stands so prominently before the public to see that its special investigations, if made at all, be more worthy of the body that authorizes them.

Reviews and Notices of Books.

Medical Diagnosis, with Special Reference to Practical Medicine: a Guide to the Knowledge and Discrimination of Diseases. By J. M. Da Costa, Prof. Pract. Med., Jefferson Medical College, etc., etc. Fifth edition, revised. Philadelphia: J. B. Lippincott & Co. 8vo, pp. 924.

The fifth edition of this work shows, by the careful revision it has received, that its author has been fully alive to his responsibilities, and has spared no pains to keep up the work to its former high standard. Many chapters have been virtually re cast, and some have been almost re-written, particularly those on the blood and nervous system. The general plan of the work is the same. The salient points of a disease and their dependence upon modifying conditions are studied in a manner to help the practitioner to understand the principles upon which diagnosis is founded, and to apply these principles to the requirements of individual cases. The work may now be considered to comprise the entire field of medical diagnosis, and to give the results of the rare and ripe experience of an accomplished medical scholar.

Account-Books for Physicians. U. L. Hitchcock (51 West Twenty-ninth Street, New York).

Mr. Hitchcock has published, on a somewhat novel plan, a set of account-books for physicians. The day-book is divided into twelve separate parts representing the respective months. Each part is suitably ruled horizontally with double daily lines for the credit and debit account of each patient, and a corresponding account of respective totals is footed up at the end of each month for each patient. These little books are mere pocket-sized pamphlets with stiff cover, and can be conveniently carried in the smallest possible compass. With this set is an office journal of large size, which is for the office table. Its general plan of arrangement is the same as that of the day-book. At the end of each month the accounts are posted in the ledger, double horizontal lines being allowed for the credit and debit accounts of each patient. Blanks are left for balancing at the end of each quarter, and the account of each patient from quarter to quarter throughout the year can be told at a glance. Altogether the set is very simply systematised, and will serve a useful purpose to every physician who desires to be his own bookkeeper. They are so arranged as to last a physician in ordinary practice for six or eight years—a very commendable feature in books of this sort.

A Treatise on Diphtheria. By A. Jacobi, M.D. New York: Wm. Wood & Co., 27 Great Jones Street. 1880.

This compact and readable little volume appears to contain about all that we need to know just now on the literature of diphtheria, and it is certainly gratifying to find that out of this confusing mass of conflicting statements and opinions some important items of progress can be hammered out.

For the last twenty years or more the author has been an active contributor to the subject of diphtheria, and no one certainly is so well provided with the information and acumen necessary for giving us a judicial survey of the field as it stands at present. Accordingly, we turn with pleasure to his brief but decisive statements on the topics which have occasioned so much controversy. Are "croup" and diphtheria identical? he disposes of in the affirmative, by showing that the alleged points of difference rest upon so slender a foundation, clinically, that one could not safely base a diagnosis upon them, while the pathological findings are precisely the same. The microphytic theory of the disease, as propounded by Oertel and others of the German school, is simply not sustained by recent investigations, so that the verdict of "not proven" forces them either to offer better arguments or withdraw the theory altogether. The author evidently inclines to the idea that diphtheria is a disease of local origin with secondary septic manifestations, and in support of this view he adduces the facts: first, that treatment addressed to the site of the lesion on the mucous membranes is calculated to abort the disease; and second, that experiments on inoculated animals indicate that the results are similar to those produced by the inoculation of any organic matter. Again, fibrinous exudation can be produced by any local irritant of the mucous membranes capable of producing intense inflammation, and it may be diphtheritic membrane, ammonia, cantharides, or other substances. The inoculated disease in rabbits, according to Wood and Formad, Curtis and Satterthwaite, produces either an acute septic disease, or a more chronic tubercular, with little or no tendency to exudation in the respiratory tract. We would suggest at this point the desirability of prosecuting further experiments on dogs rather than on rabbits. The former have the idiopathic disease; it may be a question whether the latter are ever so affected. In this connection it is interesting to observe that the author

cites quite a number of instances in which the disease has prevailed among cattle, and alludes to the possibility of its being communicated from cows having "mammitis" or caked bag (garget), as claimed by Power, of London.

Dirt and filth, according to the author, are not causes of diphtheria, but active factors in its production. They are the "breeding-places," and as such should be guarded against, because lending vitality and force to the contagious principle. In treatment, alcoholics are important, and the patient may take from two to twelve ounces daily, according to circumstances. Chlorate of potassa is dangerous, and its indiscriminate use has led to attacks of nephritis as indicated by the appearance of albumen and hyaline casts in the urine. Chloride of iron is warmly recommended, and a child one year old should take a drachm a day, in divided doses at frequent intervals Local treatment, however, is of the first importance. Laryngeal diphtheria is fatal in almost all cases unless tracheotomy is performed, though then the mortality ranges from about 90 per cent. to 40 per cent. When the epidemic has a septic character the average mortality of such cases is greatest. The poison of the disease cannot be neutralized by antiseptics taken internally. An amount necessary to overcome the poison would certainly be fatal to the unhappy subject.

THE DESCRIPTIVE ATLAS OF ANATOMY. Containing five hundred and fifty figures. Phila.: J. B. Lippincott. London: Smith, Elder & Co. 1880.

THIS is an atlas of somewhat imposing appearance, and contains ninety-two royal quarto plates with five hundred and fifty figures. It is without any descriptive text, and has no author's name upon the title-page. The object of the work, as stated in the preface, is to afford the student an opportunity of seeing at a glance the arrangement and relation of the different organs, the names of the latter being printed upon the same. The figures themselves are correct in drawing, but are evidently very old or else badly printed, presenting a heavy, blurred look, which is far from artistic or inviting. In many instances the names of the organs on different parts of the figures are so indistinct as to be unintelligible. Altogether, we think the work falls far short of the intentions of the publishers.

LECTURES ON THE SURGICAL DISORDERS OF THE URINARY ORGANS. By REGINALD HARRISON, F.R.C.S. Second edition. London: J. & A. Churchill. 1880. 8vo, pp. 394.

THE present edition of Mr. Harrison's work has been considerably enlarged as compared with the former edition, and contains a proportionate amount of valuable material bearing upon the treatment of genito-urinary disorders. Compared with the former edition, it embraces a larger field, and hence has a more extended area of application to the wants of the practical surgeon. The arrangement into lectures gives the author a latitude for expression and an ease of style which he uses to the best advantage in presenting each subject in a very plain and very practical light. The subject of stricture in all its forms is admirably set forth, the diagnosis of different forms is clearly made, the treatment suited to each intelligently given and illustrated by many interesting cases. The same may, in a general way, be said of the author's remarks on retention, suppression, lithotomy, lithotrity, and litholapaxy. The lecture on surgery of the kidney will particularly repay perusal. Tumors and ulcerations of the bladder are treated respectively in the twenty-seventh and twenty-eighth lectures, while treatment of the deformities of the penis and of varicocele close the volume.

Altogether it is a very readable, practical, and instructive work upon this branch of surgery, and cannot fail to be of great value to every one called upon to treat diseases of the genito-urinary organs. The book is in keeping with Churchill's publications in being elegantly printed.

PHOTOGRAPHIC ILLUSTRATIONS OF CUTANEOUS SYPHILIS. Forty-eight plates from life. By GEO. HENRY FOX, A.M., M.D. New York: E. B. Treat. 1880. Parts 1, 2, and 3.

This work, which will consist of twelve parts, may be considered as a continuation of the photographic illustrations of non-syphilitic eruptions lately completed by the author. It is intended to make in the present series a complete set of representations of the characteristic skin-lesions of syphilis, and accompany the same with explanatory text. The first three numbers of the work are before us. They are printed on fine paper, royal quarto size, and each number contains four beautifully executed hand-colored photographs of some of the varieties of syphiloderma, principally from the erythematous and papular groups. Each illustration is sharply defined, carefully colored, and represents the leading features of the respective forms. The descriptive text is practical in character, presenting chiefly those points bearing more particularly on diagnosis and treatment. If the work continues as it has commenced, it will be invaluable to every practising physician, but more especially to such as are deprived of clinical advantages.

TRANSACTIONS OF THE AMERICAN MEDICAL ASSOCIATION. Vol. xxxi. Philadelphia. 1880. 8vo, pp. 1,153.

THIS volume, larger than usual in size, contains the proceedings of the meeting of the association held in New York last June. The papers published, of which there is a large number, comprise every department in medicine or surgery, and give the volume a varied, if not always an interesting feature. It is impossible to review the volume in detail, as space will not permit; but, viewed as a whole, the published transactions can hardly be claimed to represent the recent progress in American medicine, or be considered as the exponent of the advanced thought of our pioneer workers. We do not remark thus for the purpose of detracting from the value of many excellent and practical papers to be found in this work, but rather as a general criticism applicable to the doings of the association, more especially during its recent meeting. It is not fair to blame the Committee of Publication for any shortcomings as regards the general make-up of the volume, as they are, as a rule, very discreet when they are allowed to exercise their judgment. But in the vast majority of cases the association, or its sections, deliberately order the papers published in full, without knowing their value, and thus swell the transactions to an unwieldy bulk, while not adding an iota to their value. There is altogether too much wholesale ordering for publication of papers, which must be stopped if the transactions would be made what they ought to be.

Then, again, there is too much lack of system in the presentation of papers at the different sections, and too little regard paid to the real value of said

papers. The consequence is that much worthless material appears upon the minutes, and many really trashy papers actually find their way into the yearly volume. The present volume suffers considerably on these accounts, but it has enough of good about it to save its place upon the shelves of the working practitioner, and be consulted by him with profit. It is published in the usual style and contains the usual appendix, in which is the code of ethics, list of members, plan of organization, etc.

Ringworm: its Diagnosis and Treatment. By Alder Smith, M.B., Lond. Philadelphia: Presley Blakiston, 1881.

Dr. Smith devotes the most of the space in this very complete monograph to a discussion of the treatment of ringworm. In recent stages the use of some vesicant, or of carbolic glycerine, is recommended; later in the disease oleate of mercury, or the artificial production of kerion by use of croton-oil, has to be resorted to. The author's experience makes his recommendations authoritative, and his book must be considered a very useful contribution to dermatology.

Rocky Mountain Health-Resorts. An Analytical Study of High Altitudes in Relation to the Arrest of Chronic Pulmonary Disease. By Charles Denison, A.M., M.D. Second edition. Boston: Houghton, Mifflin & Co. 1881.

Dr. Denison's work on the Rocky Mountain Health-Resorts was the first attempt to make any thorough scientific study of the therapeutic effects of high altitude in this country. The work was fairly well done, and it deserves the popularity it has gained.

In its first edition, however, it was deficient in scientific and clinical data, and was far from settling satisfactorily the real therapeutical value of the Colorado climate. There are no additions or changes in the present edition.

Yellow Fever. Its Ship-Origin and Prevention. By Robert B. S. Hargis, M.D. Philadelphia: D. G. Brinton, M.D. 1880.

We have in this monograph a forcible presentation of the view that yellow fever is a nautical disease—a view that has now some very strong supporters.

Drainage for Health, or Easy Lessons in Sanitary Science. By Joseph Wilson, M.D. Philadelphia: Presley Blakiston. 1881.

Dr. Wilson presents the subject of drainage in as pleasant a manner as possible, and his book will no doubt prove a useful one, especially to the non-medical public.

On the Construction, Organization, and General Arrangements of Hospitals for the Insane, with some Remarks on Insanity and its Treatment. By Thomas S. Kirkbride, M.D., LL.D. Second edition, with revisions, additions, and new illustrations. Philadelphia: J. B. Lippincott & Co. 1880.

This work, now in its second edition, has established itself as high authority on the subject which it discusses. The principles in hospital organization and construction which it recommends, are, for the most part, based on the recommendations of the American Association of Insane Asylum Superintendents, and they partake of the conservatism of that body. The matter of the book in general consists of that which a hospital superintendent needs to know, and should be capable of writing upon. There is little that indicates any special medical knowledge. Indeed, Dr. Kirkbride rather scoffs at medical accomplishments in an insane asylum superintendent.

The illustrations and general typographical appearance of the book are very superior. The book must be quite essential to all engaged in constructing, organizing, or conducting insane asylums.

On the Use of the Cold Pack, Followed by Massage in the Treatment of Anæmia. By Mary Putnam-Jacobi, M.D., and Victoria A. White, M.D. New York: J. P. Putnam's Sons. 1880.

Whatever be the practical merits of the mode of treatment described in this book, the manner in which the subject has been worked up by its authors cannot but excite admiration. A careful study of symptoms, a laborious investigation into the physiological changes that took place in the patients under treatment, and an exhaustive discussion of the meaning of these changes, are the features of the book. It is, in spirit at least, a model of the style in which a problem in physiological therapeutics should be studied. At the same time there is a good deal in the way in which the subject is presented that will arouse the reader's impatience. There is a lack of clearness and directness in the discussion of the problem. The author has the tangential habit, and lacks the faculty, of keeping the argument strongly before the reader. Side-issues are, in the form of suggestions, contingent possibilities, exceptions, and reservations, crowded into the foreground. We do not say that the author is obscure in any of her details, but the monograph as a whole has the fault that at the end it leaves the reader in great doubt as to the exact line of thought he has been following, so many different lines have been brought in. The author pauses to observe that intestinal atony may affect the (hypothetical) peristalsis in the muscular fibres surrounding the (undemonstrated) canals in the villi, thus diminishing absorption. This is almost the pedantry of science.

Again, we find the writer (who is Dr. Jacobi) involved in a discussion of what causes the increased secretion of urine after the pack. This is attributed in part to the consumption of carbo-hydrates and fat. Considering the fact that the bodily weight increases, and the total daily amount of urine is not affected under the pack, while the variation in excretion of carbonic acid was not measured, such an hypothesis is only, by an intrusive speculation, a kind of thing which pervades the book too much for a therapeutical treatise. We regret, with the author, that that particular instrument of precision, the hæmitometer, which would have been most useful in a scientific study of anæmia, was not employed.

In a final summary we are told that the cold pack meets the following indications in the treatment of anæmia: 1, it first stimulates the peripheric nerves; 2, it causes an oscillation of the blood, first from without inward, and then the reverse; 3, the radial pulse is slackened and the tension lowered.

A large number of other physiological changes are brought about, and conclusions regarding them are presented; but the great indication in anæmia, an increase in the hæmoglobin, is only inferentially established. There are, however, a number of clinical histories given which show that the method is capable of producing excellent results.

Our criticisms regarding this work would lose much of their weight if its title were "the physiological effects of the cold pack and massage;" for the book is a physiological monograph essentially,

and as such, in spite of a tortuous style, it cannot receive too high praise. Few readers can fail to be instructed and interested by its rich display of physiological and therapeutical knowledge, as well as by the full acquaintance with the methods of scientific research which it shows. It is by studies like the present one that scientific medicine is to be advanced; and we can only regret that American medical literature contains so few of them.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 22, 1880.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

CANCER OF THE BREAST—ABSENCE OF LOCAL DISSEMINATION—SECONDARY DEPOSITS IN THE LUNGS, PLEURÆ, LIVER, AND INTESTINES.

DR. E. C. WENDT presented a specimen of the above with the following history: Mrs. J. B——, aged forty years, admitted to the St. Francis' Hospital November 19, 1880, in the service of Dr. Howe. The patient's previous history and clinical record were devoid of special interest or importance. About three years ago the left breast was invaded by a cancerous neoplasm, which began to ulcerate last April and was removed piecemeal by an irregular practitioner. She developed symptoms of metastatic deposits in the internal organs, and died of exhaustion on the 20th of December.

At the autopsy the site of the mammary tumor appeared as a flat, open surface, without distinct ulceration. At the periphery of this rounded spot recurrent nodules were seen. The clavicular, axillary, and cervical lymphatic glands were found unaltered. The costal and parietal pleuræ showed numerous hard deposits of various sizes. On the left side, however, the portion of the pleura immediately beneath the former tumor was quite free from these nodules, and this immunity from disease extended for some distance beyond the boundaries of the mamma, leaving a large smooth surface. A similar area, with absence of secondary nodules, was not elsewhere found. The lungs contained numerous carcinomatous nodules, but they were found in much greater abundance on the right side, the mammary tumor having been on the left.

The liver showed many tumors, and its left lobe was unusually enlarged by a hard, cancerous mass.

In the other organs marked changes were not discovered, except in the omentum, mesentery, and serous coats of the intestines, which were sprinkled over with small cancerous granules.

Mammary cancer usually progressed by peripheral invasion of adjacent tissues and extension along the lymphatics or blood-vascular sheaths. In the present instance it appeared that a more circuitous route had been chosen. Local infection was the rule, but in this case it seemed to be entirely absent, except in the skin around the place occupied by the tumor. The absence of glandular contamination in the vicinity of the tumor, together with the fact that widespread and large metastatic deposits were encountered elsewhere, made this case an interesting and exceptional one.

CIRCUMSCRIBED EMPYEMA—GANGRENE OF THE LUNG.

G. D——, aged twenty-seven years, Ireland, clerk, was admitted into the Presbyterian Hospital, under the service of Dr. Alexander Hadden, December 6, 1880. The patient, though denying syphilis, had been intemperate and an inmate of an inebriate asylum, which he left in order to enter the hospital. Six months previously he was attacked with an obstinate diarrhœa, which lasted two months. Previous to the present attack had never had any pulmonary trouble. Three days before admission he was taken with nausea and vomiting, but there was no rigors, though the temperature subsequently rose, and there was excessive prostration. After twelve hours, severe dyspnœa set in, with lancinating pain in the right axillary line. Cough was accompanied by expectoration, which was muco-purulent for twelve days, and subsequently bloody.

On admission, his temperature (axillary) was 101.3° F.; pulse, 120; respiration, 48. During the subsequent illness the temperature-curve presented great variations, falling on three occasions nearly to the normal. Respirations, however, never fell below 32. Dyspnœa at this time was great, and the pain in right side was increased by coughing and a full inspiration; voice very feeble; normal resonance over left lung, anteriorly and posteriorly; slightly exaggerated resonance over the whole anterior surface of the right lung; dulness, amounting nearly to flatness, below the fourth rib posteriorly, and below the third rib in the axillary line, with absence of voice and breathing-sounds. Under the use of dry cups, febrifuges, and sedatives, the dyspnœa abated somewhat, and the cough was less annoying, and on the day following (December 7th) there was also less pain. The expectoration now became very profuse, and had a prune-juice color. No permanent amelioration of the symptoms was effected, however, and on December 11th, the sixth day of treatment in the hospital, he had fallen into a typhoid state. There was muttery delirium, involuntary passage of urine and fæces, with sordes upon the gums, and a brown tongue. On the 16th, four different attempts were made to draw off some of the fluid from the pleural cavity, but they all failed. The patient died on the 18th, at 3.30 P.M.

At necropsy, twenty-one hours after death: rigor mortis well marked; body well nourished. *Thoracic cavity:* one drachm of fluid in pericardial sac. Heart-substance and valves normal; weight, nine ounces. On examining the right pleural sac a circumscribed collection of matter was found walled in by a thick layer of plastic material. The superior limit of the cavity corresponded to a line drawn obliquely from the seventh rib in the median line to the angle of the fifth, the lower limit being the diaphragm. Over the second, third, and fourth ribs, just interior to their angles, there was a large circular ulcerated spot involving the pleura, but not the underlying tissues. It measured two inches in diameter. From the purulent collection a sinus led into two gangrenous cavities located in the lower lobe of the lung. There was no continuity between the process in the pleura and that in the lungs, and the latter appeared to be produced mechanically by a bursting of the pus through its wall, thus seeking an exit by the respiratory passages. The lower lobe of the right lung was consolidated, "hepatized." Microscopical examination of the most consolidated portion around the gangrenous cavities showed the vessels to be distended with blood, the air-vessels filled with cellular

elements, and the interstitial tissue deeply pigmented, apparently with carbon pustules. The left lung was normal. *Abdominal cavity: spleen* normal in appearance; weight, five ounces. *Kidneys* weighed, right, five and a half ounces; left, six ounces; capsule thin and slightly adherent. Both were congested, the right more than the left. Cortical substance fatty, especially the right. On microscopical examination, a slight increase in the interstitial tissue was detected with fatty degeneration of the epithelia. *Liver:* weight, fifty-eight ounces; a little fatty. *Brain:* vessels of the meninges filled with blood; dura mater, at convexity, adherent; brain-substance pale.

In answer to a question from Dr. Satterthwaite, Dr. Porter stated that the pneumonia was of the croupous variety.

AMORPHOUS DEPOSITS IN AMNIOTIC SEPTUM.

Dr. Partridge presented a specimen of the secundines of a twin pregnancy, and called attention to several amorphous deposits in the amniotic septum. These deposits averaged three-quarters of an inch in diameter, and were from an eighth to a quarter of an inch in thickness. They were examined microscopically by Dr. Peabody, who pronounced them to be the remains of a recent clot. The question of interest was how a clot could have found its way in that locality. During the third month of gestation the patient was threatened with a miscarriage, and it might have been during that period the effusion occurred. Some of the deposits were situated quite a distance from the edge of the septum, were apparently isolated, and contained a considerable amount of coloring matter.

Dr. Partridge presented a second specimen which consisted of the products of gestation at the period of eight weeks. It showed the reflection of the amnion upon the umbilical cord; also the remains of the umbilical vesicle, and the commencement of the formation of casts of intestine.

DISSECTING ANEURISM.

Dr. Peabody exhibited the upper part of the femoral artery removed from a patient whose thigh had been amputated in consequence of a railroad injury. The lower third of the thigh was severely crushed, and a false aneurism resulted necessitating removal of the limb on the second day after the injury. The internal and middle coats of the artery were ruptured in one situation, and the external coat in another, causing a dissecting and diffused aneurism in the neighborhood of the injury.

CURIOUS DEFORMITY AFTER COMPOUND FRACTURE OF LEG.

Dr. Peabody also presented a specimen of curious deformity after a compound fracture of the leg. The patient was an engineer who fell from the elevated railroad with his engine, striking upon the pavement. The tibia and fibula were broken in several places, and the soft parts were extensively injured. The patient did not come under observation until a considerable time after the accident. It was then impossible, on account of the condition of the soft parts, to attempt to bring the bones in position. The result was a striking deformity caused by the faulty union of the fragments. Amputation was performed ten months after the accident.

On dissection of the limb the tibia was found to have been broken in three places, and the middle fragment was united at right angles with the other two. The fibula, also broken in three places, was united by its upper and lower fragments, while the middle fragment was joined by its lower extremity to the side of the lower fragment, and by its upper extremity to the middle fragment of the tibia. The leg was shortened about six inches.

The society then went into Executive Session.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 4, 1881.

Dr. T. A. McBride, President, in the Chair.

A case was presented by Dr. W. J. Morton, showing the effect of

MAGNETS IN THE TREATMENT OF HEMIPLEGIA.

The patient, a woman aged twenty-two years, had had an attack of cerebral hemorrhage two years before. This had left her with greatly impaired motion and an almost complete loss of sensibility on the left side. The left arm and hand had become flexed and capable of but little motion. The toes dragged in walking and she could not put the heel on the ground. One magnet was applied on the leg over the stocking, and another on the upper arm. They were kept on for about an hour, the treatment not being repeated. The patient speedily felt a return of sensibility, and in a short time it was almost completely restored. Motion was not affected by the magnets, but was improved by the use of electricity.

The paper of the evening was then read by Dr. W. J. Morton, the title being

THE TOWN OF GHEEL, BELGIUM, AND ITS INSANE.

The town of Gheel, according to tradition, became a resort for the insane so early as the seventh century. The patients first came in order to worship at the shrine of St. Dymphna, which had acquired high reputation for its cures. As the fame of the town grew, the insane flocked to it in greater numbers, and the inhabitants gradually adopted the custom of taking into their houses and homes the afflicted persons who came to pray for cure at the sacred shrine. Definite knowledge of Gheel, as a home for the insane, dates from the twelfth century. Since that time its reputation has never waned, and in the past century has steadily increased.

Gheel is a commune in Belgium, numbering about 12,000 inhabitants, who are a mixture of Germans and Gauls. It has no special industry, but the population is principally occupied in agriculture, domestic lace-making, and caring for the insane. They are frugal and industrious, and the general spirit of the town is peaceful and calm, without being exactly behind the age. Most of the population is centred in a town, about which hamlets are scattered the distance of about a mile. Among the 12,000 inhabitants there are about 2,000 domiciles, of which nearly 1,000 receive insane patients. All classes of the insane are received at Gheel, except such as require continual restraint, and those who are suicidal, homicidal, or incendiary. The insane population numbers now about 1,600, and is steadily increasing. At the beginning of the century it was 400; in 1868 it was 1,035; in 1876, 1,383.

Of this insane population seven-eighths are Belgians, and the rest Hollanders, Germans, French, and English. About 200 are paying patients; the rest are paupers.

The Gheel insane had no regular medical service

until the year 1851, when the Gheel system was thoroughly reorganized, and placed under government control.

THE ADMINISTRATION.

of all the affairs of the insane now rests in the hands of a "superior commission," composed of: 1, the governor of the province, or his delegate; 2, of the attorney-general; 3, of the judge of the canton; 4, of a physician appointed by the government; 5, of the burgomaster of the commune; and 6, of five members nominated annually by the minister of justice. This commission has a salaried secretary, who has very important duties. He makes the reports, conducts the correspondence, has charge of moneys and the books, and is steward of the central infirmary. Any outside towns or asylums having twenty-five or more patients at Gheel may be represented by a delegate. The medical inspector also has a consulting voice. The real working part of the commission is made up of the five appointed members mentioned last. These meet once a week, receive reports, disburse money, distribute the patients, and see that the laws and regulations regarding the care of the insane are carried out.

NOURRICIERS AND HOSTS.

Those families which are willing to receive patients must be duly registered, and must have shown evidences of good moral character and ability to provide proper accommodations and food for their insane charges. The families that receive paying patients are called hosts; those that receive paupers are called "nourriciers," or nurses. No family takes more than two patients. Great care is taken to see that these patients are put in surroundings as much like those they were previously accustomed to as possible. A great many precautions are taken to see that the patient is not overworked, and is well cared for in every way. Thus there are four "section guards," who patrol the special districts assigned them, and make daily reports to the medical inspector.

THE MEDICAL SERVICE

is under the charge of a medical inspector, Dr. Peeters, aided by three physicians, who have charge of the three separate sections into which the town is divided. Each section physician visits the curable patients at least once a week, and the incurables once a month, their visits being registered in a book. He makes a monthly report to the medical inspector, who in turn reports to the superior commission. The medical inspector makes visits whenever asked, and must, in any event, visit every patient at least three times a year.

THE INFIRMARY

resembles in its main features the ordinary closed asylum. Its purpose is to afford the usual hospital treatment to patients attacked with incidental diseases; to care for the very infirm, and to take a brief charge of cases that suddenly develop a condition of excitement which requires for short periods continuous and special watchfulness and restraint. The patient's stay in the building is expected to be temporary. The business management is under the direction of a steward, the secretary of the commission. The medical duties are entirely distinct from the executive, and are performed by the medical inspector. There were, at the time of Dr. Morton's visit, thirty-seven patients in the building out of an insane population of 1,603. No mechanical restraint was employed.

THE INSANE IN THEIR HOMES.

The liberty which patients apparently have in their homes is really hedged in by carefully considered restrictions, and by systematic care and watchful restrictions. Not only is each patient cared for by his own particular village guardian, but the whole community co-operatively act as voluntary guardians In a place where nothing is concealed, abuses are not likely to thrive. Public opinion and open dealing are the patient's safeguards. And to this traditional relation between villager and patient must be added the surveillance of regularly appointed officers. The speaker believed that the assertions of Dr. A. M. Shew, in his pamphlet on Gheel, that there was an absence of medical care and an almost unlimited opportunity for the abuse of patients, were entirely incorrect. Abuse was in reality impossible, and the medical care was very skilfully directed. The insane are classified into the "dirty," the "half-dirty," and the "clean." For the first class is paid about nineteen cents a day; for the second, eighteen cents; and for the third, sixteen cents.

About four-fifths of this money goes to the villager; the rest is for medicines and medical attendance. These rates are lower than at any other establishment in Belgium.

The speaker described an inspection which he made of a large number of houses, with especial view to seeing the quarters provided for the patients. These he in every case found to be clean, well ventilated, and supplied with a good bed. The statement of Dr. Shew, that the patients were in many cases stowed away in garrets, lofts, and out-of-the-way nooks and corners, was not corroborated by the speaker's observations. A little book is kept by the nurse or host, in which is a record of the patient's history and of the visits paid by the doctor.

Dr. Morton related several cases taken from the records of Dr. Peeters, showing the good effects of the Gheel system upon insane patients brought to the colony.

The number of escapes range from seven to twelve annually. The villager in charge is responsible for his patients, and has to pay for the expense of capture. Patients who escape are quickly captured and returned.

Acts of violence are comparatively rare. Only three instances are known. One of these was a homicide committed in 1840. The other two were acts of personal violence, not resulting seriously. Three suicides have occurred since 1875. Offences against morality are almost unknown.

THE HAMLETS.

In the suburbs of the central town, in every direction, there are groups of farmer's houses. Here a good many of the insane are also domiciled. These houses are not as well kept as those in town, but they make comfortable and healthy houses. The peasants themselves are fine specimens of physical health. Dr. Morton did not agree with Dr. Shew that the houses were damp, and the peasants overworked and under-fed. Everything showed care and kindness on the part of the peasant attendants. To look after their charges seemed to be a settled part of their daily lives.

It is difficult to get a fair estimate of the per cent. of cures at Gheel, for the proportion of incurables is very large. Thus, of 313 patients admitted in 1879,

seventy-three were received from other asylums, and all but two were absolute incurables. Reckoning, however, upon the admissions from 1853 to 1870, the per cent. of cures was 24. On the other hand, the proportion, based upon the probably acute cases admitted, was from 79 to 89 per cent.

THE "GHEEL IDEA."

The main characteristics of the Gheel system are its comparative freedom, occupation, and the family life. Gheel is probably an ideal which can never be repeated by any other nation, for the simple reason that there is but one village of Gheel removed from the world's traffic and turmoil, where the inhabitants, by reason of centuries of inheritance, have learned a patience sublime in its simplicity, a tact in management born of affectionate regard for their charges, and an absence of timidity impossible to realize until witnessed.

But though the "Gheel idea," the family system, may not be repeatable, the essence of the idea, *i.e.*, a large and reasonable liberty, healthful and sufficient employment, and accustomed and congenial surroundings, is repeatable, though not certainly in any of our great asylum buildings. Gheel teaches us the possibilities that lie in the treatment of the insane, and how woefully wide our advanced civilization is from the mark it might attain in this direction.

At the close of the reading of the paper, DR. E. C. SPITZKA presented a case of

CEREBRAL ASYMMETRY

in a monomaniac, a man aged forty-five years. His delusions had developed within the past few years. The cranium was markedly asymmetrical. In the less developed side of the face there were disturbances of motility. The point made was that the delusions and motor disturbances might lead to a suspicion that the case was one of general paresis. The disturbances, however, were undoubtedly due largely to the asymmetry, and the patient would never develop into a paretic.

Correspondence.

MORE FACTS CONCERNING THE USE OF THE METRIC SYSTEM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In the MEDICAL RECORD of Nov. 27, 1880, under the heading "Facts Concerning the Use of the Metric System," a gentleman from Massachusetts criticises some statements made in a letter on "The Americanized Metric System," published some weeks before.

Judging from his criticisms the gentleman has gone far astray in his idea of the metric system in general, and has particularly misunderstood my idea in publishing the Americanization of it. I thank him, therefore, for the opportunity given me "to rise and explain," and hope that I may be able to make myself clear.

The first statement made to which the gentleman takes exceptions is: "Most physicians appreciate the advantages of the metric system." In contradiction, he writes that not one physician in ten "*are*" using the original or "Americanized" metric system. I wrote that most physicians appreciate (and a large number are using) the metric system because my investigations warranted the statements. I have found that most physicians acknowledge that it is a model system, but nevertheless, having become accustomed to prescribing in the old way, they are unwilling to make the slight exertion necessary to a change. It is probably true that not one physician in ten is using the metric system, but even with that small proportion we have a large number using it.

However, the mere fact that not one physician in ten "*are*" using the original or "Americanized" metric system should cut no figure in the case. The principles of the metric system are either right or wrong, and unless the gentleman has better grounds for condemnation than not one in ten "*are*" using it, let him hold his peace.

Besides the two arguments which the gentleman brings up, viz., that its use is limited, and that a change is unnecessary, I have heard a third which may be well noticed here. Certain gentlemen, some of them standing high in the profession, object to the system because they say that the *standard* is wrong. When the French scientists took the $\frac{1}{10000000}$ part of the earth's quadrant, it is charged, although not proven, that they made an error, and therefore the model system which they formed on this standard is all wrong. Think of the calamity, ye who appreciate the fact that every standard of length is, to a certain extent, arbitrary!

The second statement to which the gentleman takes exception is: "The majority of the pharmacists . . . are anxiously waiting the day when they can discard the time-honored drachm and ounce,"—and in contradiction he writes: "The result of inquiry in different Eastern States is, that most druggists who have procured new apparatus have done so at the request of one or more of their patrons, and not because of any desire on their part to do away with the old system of weights and measures." The result of inquiry in different Western cities is that the druggists have procured the apparatus because they needed them to fill prescriptions written in the metric system, and having once used them and familiarized themselves with the system, they *are* anxiously awaiting the day when they can use it exclusively. One object in Americanizing and simplifying the system is to assist druggists in becoming familiar with the system, and prevent the staring of the country druggist, of which the gentleman speaks.

Again, your correspondent of Nov. 27th, misconceives, in my belief, the whole idea of the metric system when he writes "many physicians are using the new system with the honest intent of advancing science." Although the general adoption of the metric system would advance the interests of science, of art, of morals, and of medicine, yet the primary reasons why we urge its adoption by individuals are its simplicity and decimal progression. Gentlemen sacrificing themselves in "advancing science" should make a ten minutes' *study* of the system, and thereafter use it for convenience.

To the statement that others of the profession use it to appear scientific and superior to their brethren who prefer to deal with *facts* rather than hypotheses, I have nothing to reply except to say for the gentleman's benefit that the metric system is a plain, simple, and substantial fact, comprehensible by a child, and not, by any process of reasoning, an hypothesis. In answer to the question "If the 'Americanized' plan would not interfere with the original intent (?) of the system, viz., an international system of weights and measures," I will say that

several European nations (Germany and Austria) recognizing the fact that names do not constitute a system, have changed the terms in a manner similar to that suggested in the Americanization.

Not only has "the authoritative voice of the American Medical Association spoken in favor of the new system," but the Marine Hospital Service is *using* the new system to the entire exclusion of the time-honored drachm and ounce. Not only this, but the system has been adopted or recommended after mature deliberation by the National Academy of Sciences, the American Meteorological Society, the American Association for the Advancement of Science, the American Society of Civil Engineers, the United States Coast Survey, the Congress of Ophthalmologists, by the largest state and local medical societies, by leading medical schools and journals, by numerous boards of education, faculties of colleges, scientific societies, and by progressive men in every branch of science and art, and Congress has taken occasion to throw "the cloak of conservatism" around it by publishing a book of two hundred and eighteen pages, which gives a complete history of the movement in this country.

I may be an enthusiast concerning the use of the metric system, but I became one only after I had thoroughly canvassed its advantages and overcome prejudices less deeply rooted, I am happy to say, than they seem to be in your correspondent.

In my letter of Oct. 23d I did not enumerate nor attempt to demonstrate the advantages of the metric system. I will not trespass upon your valuable space to do so now. Suffice it to say, that the letter on the Americanized Metric System has been received by those who appreciate its designs; *i.e.*, the simplification of the matter, with marked favor, as the following extracts from letters to the writer will show:

Prof. Oscar Oldberg writes: "Your prescriptive blank, it seems to me, is an excellent one. The terms used in France to designate the units of the system do not constitute the system, and hence it seems to me to be quite proper to Americanize them, if thereby we can popularize the introduction of this admirable system and yet retain the one term gram to make plain its identity."

Dr. F. R. Fry, of St. Louis, writes: "I wrote last year about 5,000 recipes in this system, and can testify to its advantage; but think that the whole advantage is due to the fact that it is a decimal system. I like your idea first-rate for a unit; fifteen grains, or one-fourth drachm, is more convenient for translation from the present system."

Now, sir, in conclusion, allow me to state that I have no desire to traduce the time-honored drachm and ounce. They are good weights and measures; but having found in the metric system a simpler, and, therefore, better method of prescribing, I shall adhere to it until convinced of my error by arguments other than your correspondent has brought forth.

I forget, perhaps, that my lot has been cast and my inquiries made in the benighted West, while the gentleman "has charge of the health and life of the American people," residing among the spokes of the Hub, with its Bureau for the Promotion of Meteorological Knowledge.

Geo. N. Kreider, M.D.

Springfield, Ill.

A New Hospital is soon to be erected in this city, in connection with the Sheltering Arms.

RECORD OF SOME INTERESTING CASES IN PRIVATE PRACTICE.

I. Two cases in which morphine was used hypodermically to control the spasms of young children.

II. Secondary post-partum hemorrhage, controlled by a bandage of adhesive plaster.

III. Large abdominal abscess cured by two aspirations. (Abscess of broad ligament?)

To the Editor of The Medical Record.

Sir—As the hypodermic use of morphine to control the spasms of young children is somewhat new, I should be glad to record two cases in which it was successful.

Case I.—I was called to see a strong boy of three years, in terrible convulsions. Pulse rapid, breathing irregular, occasional twitching of muscles between the spasms, which came on every four minutes. His bowels had moved. He had vomited. He had been placed in warm mustard bath, but his spasms still continued and were most terrible. It was late, and not deeming it advisable to send for chloroform, I gave the boy a hypodermic injection of one minim of Majendie's solution of morphia. It had no effect. I gave him another minim, and waited. The convulsions were moderated, but not entirely controlled. I gave him another minim and a half. His convulsions ceased, his breathing became regular, and he lay in a gentle sleep. His pupils were not contracted. I ordered his bowels to be freely opened, and directed a mixture of bromide of potash and fluid extract hyoscyamus to be given in suitable doses as soon as he became uneasy or awoke from his sleep. I saw the boy daily for some time, and he had no return of the convulsions. I may state that his second passage contained some undigested substances.

Case II. was a boy aged seven years. He was subject to convulsions following scarlet fever three years before. I ordered a hot bath before I saw the boy, and when I reached the house he had vomited, but the spasms were still terrible. His mother said they were worse now than ever before. I immediately resolved upon morphine injections, and in gradual doses and at regular intervals gave the boy between sixteen and seventeen minims of Majendie, when his convulsions were at last controlled. I may state that this solution of Majendie contained some atropia. The boy's pupils did not contract to any appreciable extent, and as he even now had some slight contractions of the fingers of his left hand, when moved, I ordered a full castor and turpentine injection to be given, and followed by bromide and chloral by the rectum, and directed that a diuretic mixture should be administered when he regained consciousness. I did not see the boy again; but directing his mother to send for her own physician that day, and asked her to inform me as to his state that night. She called next day, and said the boy was doing well. I suppose my medicine was continued, but I heard no more of the case. I believe there is a marked tolerance of morphine in all spasmodic attacks of children, and especially when the convulsions are dependent upon renal trouble.

Secondary post-partum hemorrhage—three cases.—By this I mean a state of affairs as follows: The uterus after the delivery of the placenta contracts firmly; but in from half an hour to two hours the patient complains of a warm flow, and her napkin is found to be wet with fresh blood. This, if not at-

tended to at once, may end in a severe internal hemorrhage, due in measure to the uterus, by slight, but frequent relaxations, becoming filled with clots, then not having power to expel them, the womb is held open while the blood rushes forth from its sinuses. It follows then that the womb, even after firmly contracting, frequently relaxes, and in certain cases, where the blood does not easily coagulate, this relaxation causes a small but persistent flow, which in many cases ends in death. The first case of this character I ever saw was a lady, who, after giving birth to twins, was suffering from an intermittent flow of blood all day. The womb contracted, indeed, but it again and again relaxed. The delivery took place at 12 mid-day, and at two o'clock next morning I was called to assist my father and the medical gentleman who had delivered her. The patient had a faint, rapid pulse. Her womb on being held firmly in the hand contracted like an india-rubber ball; but after holding it from three to five minutes, you felt it becoming soft and, although after a little rubbing on the fundus it again contracted, blood was continually flowing during these intervals. Ergot had been given. Electricity had been used, and was being used at that moment. In fact it was easy to cause contraction, but thus far impossible to hold it. Finally, on my father's suggestion, a graduated compress of adhesive plaster was prepared. This was placed upon the womb, which was then crowded backward and upward on the brim of the true pelvis, and to the right of the middle bone of the sacrum, and held by a bandage of adhesive plaster about four and a half inches broad, and which was made to girdle the body as firmly as it could be drawn. We were happy to find that all hemorrhage ceased, and did not again return.

Case III. was a case of similar character. The woman had been delivered, and the same kind of flow had been taking place all day. The battery was used. Iron had been injected. The flow still continuing, the patient's husband had become alarmed. After using the battery for half an hour, and finding that a small but dangerous flow was still occurring, I advised the use of the adhesive bandage and compress. It controlled the hemorrhage.

Case IV. was my own. I feared hemorrhage, and although the womb contracted well, I waited an hour, when, to my alarm, the blood commenced to flow and the womb to intermittently contract and relax. I tried hot water, but not succeeding in making the womb contract for any length of time, I used the bandage, and all hemorrhage ceased. I may mention that in this case I used ice, conjoined manipulation, and hot water, all of which secured contraction, but none secured a permanent contraction.

Abscess of broad ligaments.—A lady called upon me last summer who just twenty-three days before had been confined. She complained of a swelling of the abdomen. Her pulse was rapid and her pallor extreme. Her history was as follows: Four days after delivery she had a chill, and from that period she began to swell. She at no time had much pain, nor had she much to complain of now save her rapidly increasing size and loss of appetite. I suspected dropsy, and putting her on some simple remedies, I examined her urine. It was normal. She said she had never used stimulants. By waiting a few days, it was found her size increased by as many inches. My father, Dr. John Burke, saw her with me, and it was resolved to aspirate. The needle was introduced midway between umbilicus and the pubes on the middle line, and in the middle of a flatness which was distinctly localized but which was of enormous extent. A thin pus flowed through the needle and it continued until we had drawn off two gallons of pus. The very courageous patient bore it all without flinching, and so great was her joy at being relieved that five days after the operation she got up, contrary to orders, and had another chill, when the abdomen commenced to swell again. I again aspirated, and drew off a gallon of pus of the same character. She was now put upon quinine in large doses and firmly bandaged. In aspirating a second time I could easily feel the walls of this abscess going down into the pelvis, and when the fluid flowed more slowly, the needle on being pressed downward and backward caused the flow to increase. Two weeks in bed sufficed for a cure. There has been no return of the trouble up to the present time.

MARTIN BURKE, M.D.

147 LEXINGTON AV.

THE ORIGIN OF ENTERIC FEVERS IN ISOLATED RURAL DISTRICTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—Under the above caption, Dr. R. Bruce Low has an article in the *British Medical Journal* of November 6, 1880. The doctor writes "as a country practitioner in an isolated and thinly-populated rural district."

In discussing the mode of infection, the writer rules out contaminated milk and water, sewer-gas, and specific infection. Of one other sanitary condition he speaks as follows: "The system of excrement disposal in these parts is the old-fashioned garden-privy. In many cases this is neglected and allowed to remain unemptied for long periods. Accumulations of filth, level with the seats, were often found when inspecting the back premises of the houses where enteric fever had appeared."

Now, let us take the doctor's Case I., and draw the inferences therefrom.

"A young tailor, aged nineteen years. For a year previous to his illness from fever he had suffered from occasional attacks of diarrhœa, the last attack being three months before he took to his bed with typhoid. With the exception of a few days at home with diarrhœa, he had been steadily at work. The work-room was close and ill-ventilated. Here he worked with two other apprentices, having his meals with his master, but going home to sleep. The lad was dirty in his habits, sometimes not washing his face for three or four days at a stretch. He became ill and unable to work.

"The medical attendant was called in, and diagnosed typhoid fever. A second medical man also saw the case, and confirmed the soundness of the first opinion. The patient died on the twenty-first day, after the disease had run a typical course, but with severe abdominal complication. He had not been away from home for months; no strangers had visited at the house. There was no fever in the district, the last case having occurred eight months previously in a sequestered valley eight miles away. With this previous case there could not have been any possible communication.

"The water-supply was pure and abundant; it was piped from a distant spring to the house, but the tap had been out of order for some months, during which time water was obtained from a neighbor's tap, in whose house there had been no fever.

"There were no drains nor channels of any kind

to carry off slop-water. The slops were taken by hand across the road, and thrown into the rapid stream which ran in front of the house. The cottage was damp, dirty, and overcrowded. The garden-privy was in bad repair, the filth level with the seat. The smell was very bad. The habits of the inmates of the house were in keeping with the surroundings.

"I have seen a tubful of soiled napkins (from a child eighteen months old), with the excrement adhering to them, placed in the pantry where all the eatables and dishes were kept. This tubful of filth, I was told by one of the family, was allowed to stand for days.

"The house at all times smelt close and dirty. The child just referred to took typhoid fever after the death of the lad."

I believe it has long been accepted as a fact that the dejections of typhoid-fever patients, and especially if any putrefactive changes are going on, are capable of specifically infecting all susceptible subjects coming within their range. Based on this, I have for years gone a step further. I believe that many cases of typhoid fever, and especially in the country, are due to decomposing excreta. I have seen cases that can be explained in no other way. The case of Dr. R. Bruce Low seems to me perfectly clear. Country people are particularly neglectful of their privy vaults.

I have no doubt but that the majority of country practitioners have had cases where they have looked in vain for the cause in the drinking-water, in the milk, in the family larder, and in the pig-sty, when a visit to the privy might have explained it at once. It may be asked, how can decaying, *healthy* fecal matter produce typhoid fever? All I can answer is, how does sewer-gas produce it? *Quien sabe?* Yet it is accepted as a fact.

If country practitioners in general will only come forward and give the condition of the privy-vaults in cases where the other supposed causes of typhoid are wanting, it will not be long till we have made another stride in solving the problem of cause in typhoid fever. If clinical observers would only be half as prompt in giving their experience as pathologists are, all doubts as to medicine and science would soon disappear.

Let the readers of the MEDICAL RECORD speak, and we shall have much light.

CHARLES ANDERSON, M.D.,

CAMP ON SNAKE RIVER, KY.

HYOSCYAMIA IN SUBSULTUS TENDINUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—Allow me to direct the attention of the profession, through the MEDICAL RECORD, to hyoscyamia as a remedy for a train of nervous symptoms which I met with in a case of typhoid fever.

In the latter part of November last I was called to attend a young farmer of good habits, who presented the ordinary symptoms of commencing typhoid fever. The only symptom unusual to create anxiety was a very marked subsultus tendinum, which at my first visit was so strongly marked in the carpal tendons as to make it difficult to accurately count the pulse or estimate its quality, though the young man did not regard himself as ill enough to be confined to his bed.

For the first twelve days there was nothing more than ordinary in his daily condition, except this one symptom, which steadily became more pronounced from the first. There was slight delirium at night—a range of temperature of 100° to 101½° in the morning, with 102° to 103° in the evening. A pulse that varied but little from 68, regular and of good strength. He took an abundance of milk, which he relished, and which seemed to be appropriated.

On the twelfth day (Friday) he began to hiccup. This was continuous and very distressing from the first. It deprived him of rest and sleep. Every known remedy was tried faithfully. After exhausting my own experience and reading in combining antispasmodics and nervous sedatives without avail, I invited a counsel. Some changes were made in the plan of treatment, with the hope of controlling this distressing condition, but all to no purpose. The hiccup continued, without intermission, except a few hours at one time, when complete anæsthesia with chloroform was produced; until Tuesday evening following—four days—other unpleasant symptoms became more marked. The delirium was noisy and constant. Restraint was required to control the patient. The temperature increased to 100°, though cold sponging was practised hourly and half-hourly. The pulse increased to 120, and was feeble and irregular in rhythm. The subsultus became general—every part of the body was in a state of constant tremor, and speedy death seemed imminent.

I had obtained of Dr. John P. Grey, of Utica, a solution of hyoscyamia for hypodermic use in quieting the mental excitement of the insane, and having watched its effects in calming their excitement, it seemed to me that so potent a nervous sedative might prove of service here. I began its use in the manner advised by Dr. Grey, in his paper to the State Medical Society of last winter. The effect was marvellous. While the influence of the remedy lasted (from eight to twelve hours) there was no hiccup, subsultus, or delirium; but instead the patient slept quietly and naturally most of the time, and when awake was quiet and semiconscious. But he had become too much exhausted by the prolonged loss of rest and nervous strain to fully rally. He died at midnight on Friday; but to the last he readily responded to the effects of this remedy, so that all the distressing symptoms were relieved to the end.

Had the hyoscyamia been tried earlier, and the exhaustion of hiccup and delirium and loss of sleep been thus avoided, it seems to me more than probable that his strength thus husbanded would have carried him through to ultimate recovery.

I commend the further trial of this excellent remedy, used in the mode suggested by Dr. Grey, in the varied nervous conditions attending exhausting disease.

H. D. VOSBURGH, M.D.
LYONS, N. Y., January 5, 1881.

CREMATION IN FRANCE.—Coincident with the efforts of the British Medical Association to popularize cremation in England, a society for the furtherance of this mode of mortuary observance has been organized in Paris. The object of the society is to secure government recognition of cremation as a legal form of burial. The society has already received enough promise of support to ensure its success. The annual subscription is ten francs for the first year and five francs after that.

New Instruments.

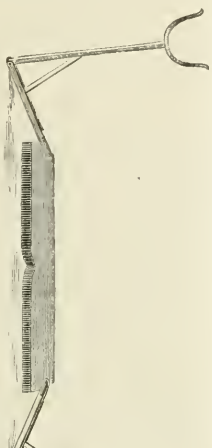
THE GYNAPOD.

By HUGH HAMILTON, M.D.,

HARRISBURG, PENN.

THE growing practice of gynecology has invented numerous specula to examine the mouth of the uterus, and other instruments to explore the interior of it, being purely mechanical, depend upon the position of the woman.

Specialists have office furniture permitting adjustment to suit their needs; but when the individuals must be attended at their homes, a bed seldom allows the patient to be placed in an accurate position. The difficulties experienced in this matter of women presenting themselves for examination on soft hair-mattresses or feather-beds prompted this apparatus or instrument.



The name gynapod, from the Greek Τα ποδι γυναικος, signifying *for the feet of a woman*, from which, by transposing and condensing, a short term, GYN-A-POD, expressive of its use, is coined.

Description.—It consists of a board having a notch in it; at each end there is an arm of forged crucible steel, fixed by a pivot admitting horizontal motion. This arm is formed of two lengths: the first, or one nearest the board, being two pieces of flat steel parallel and edgewise; at their extremity a second or crutch-shaped length is fastened, held in position by a brace—the whole folding into the first length, like the blade of a pen-knife.

Use.—The woman should lie on her back with a low pillow under her head. Direct her to sit upright, place the gynapod's notch close to the nates in a line with the anal fold, extend the arms and then have her lie down upon the board, the sacrum should be on it; erect the crutches and draw them near the thighs, then flex the knee upon the abdomen by taking the ankle in your hand until the plantar surface of the foot can be placed in the crutch; always place the limb farthest from you first—the other leg is treated similarly. The feet should be encased in slippers. This manipulation can be done under a sheet by drawing it well down, and wrapping each ankle in a corner without the slightest personal exposure. It is claimed that the gynapod puts the female in a constantly accurate position with ease to herself; permits the use of valvular or cylindrical specula; demands less stooping on the part of the physician; is of simple construction, small compass, hence portable; weighs *two* pounds, occupies 16x4½ inches; can be readily used upon a lounge or bed in the office or residence.

December 20, 1879.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 16, 1881, to January 22, 1881.

BAILY, Jos. C., Major and Surgeon. His leave of absence granted him in S. O. 188, December 13, 1880, Military Division of the Pacific and Department of California, extended one month. S. O. 13, A. G. O., January 18, 1881.

COUES, E., Capt. and Asst. Surgeon. Having reported in person, is assigned to temporary duty in the office of the Medical Director of the Department. S. O. 1, Department of Arizona, January 3, 1881.

GIRARD, J. B., Capt. and Asst. Surgeon. To be relieved from duty in Department of Texas, by Commanding General thereof on receipt of this order, and then to report in person to the Commanding General, Department of Arizona, for assignment to duty. S. O. 14, A. G. O., January 19, 1881.

TAYLOR, B. D., Capt. and Asst. Surgeon. To be relieved from duty in Department of the East, by Commanding General thereof on receipt of this order, and then to report in person to Commanding General, Department of Texas, for assignment to duty. S. O. 14, C. S., A. G. O.

MEDICAL SOCIETY OF STATE OF NEW YORK.—The annual meeting of this society will be held at Albany, commencing Tuesday, February 1, 1881.

CHEMICAL EXAMINATION OF DRINKING WATER.—The National Board of Health announces that a careful study of the chief methods in use for the chemical examination of potable water, so far as organic matter is concerned, has been undertaken.

A THERAPEUTICAL SUMMARY OF THE PAST YEAR.—New remedies have been many and various, some (few) good, many bad, most indifferent. Worthy of mention, however, are "Tonga," invaluable in facial neuralgia; sulphide of calcium in suppuration, its action being marked and reliable, grain-doses being those now admitted; the nitrites of potassium and sodium have very lately been advanced as milder in their action than amyl nitrite, but producing similar effects; ergot has been found serviceable in diabetes; pilocarpia has been found useless in hydrophobia.

which still resists all treatment; this same agent has been tried for numerous affections also, but with only meagre encouragement to rely on its influence; benzoate of soda has been recommended in scarlet fever and gonorrhœal ophthalmia. Salicylate of soda has had this said about it by Dr. Greenhow, a high authority: "Treatment of rheumatism with salicylate of soda neither prevents nor diminishes the frequency of complications in rheumatic fever." It may do a positive injury to the heart. Salicin is inefficacious; salicylate of quinine is recommended highly by Dr. Hewan. The value of cold baths in typhoid fever has become more than doubtful.—*Medical Press and Circular.*

Nostrums and the Clergy.—We are glad to notice that the *Independent Practitioner* has attacked the practice of advertising quack nostrums in religious journals. It says: "The late Dr. Thomas E. Bond, of this city, became a minister of the Methodist Church, and for several years ably edited a religious newspaper here; but he established a rule to exclude patent medicines and nostrums from the advertising department of his paper entirely. He did this, too, in several cases, at large pecuniary loss to his enterprise. But such was his determination to keep his hands and conscience clear in the premises, that he permitted no price to change his purpose of keeping all secret nostrums from the columns of his paper. This stand against quackery was taken several years after he had given up the practice of his profession. Here was an example that all clergymen would do well to follow. He not only declined to countenance secret nostrums in every way, but manfully refused to allow the endorsements of them by others to appear for pay in the advertising columns of his religious publication. There are several strong lights in which this nefarious business for extorting money from a credulous public can be seen, and in most of them the endorsing clergy occupy an unenviable position, but we must close our remarks for the present."

Humero-Costal Compression of Brachial Artery.—Dr. J. W. Howe, of this city, writes: "In the last edition of the Record you credit Dr. Zenker, of Schivelbein, with developing a '*simple method of compressing the brachial artery*' by 'humero-costal compression.' I beg leave to state that humero-costal compression of the brachial artery was first advised by me in my work on 'Emergencies,' published nine years ago, chap. i., p. 15."

Medical Books in Great Britain.—*The Publishers' Circular* states that the number of *new* books upon medicine and surgery published in Great Britain the past year is 148, the number of *new editions* 54.

Congress and Food-Adulterations.—The House Committee on Manufactures gave a hearing on the 21st inst. to George L. Angell, of Boston, upon the subject of poisonously adulterated articles. Among the subjects discussed by Mr. Angell were drugs, poisonous articles of clothing, and wall-papers. He offered evidence to show that from one-third to one-half of all the wall-papers now sold, in a great variety of colors, contain arsenic to a degree that renders their use dangerous. He pronounced against the use of glucose and oleomargarine products, and gave numerous illustrations of the danger incurred in using canned fruits, meats, and vegetables, when put up in tin. In conclusion, Mr. Angell urged the importance of providing a committee or commission to investigate the subject. Subsequently the committee adopted Mr. Beale's bill "to prevent the adulteration of articles of food and drink." This bill was reported to the House a few days later.

The Hospital Fund.—Mr. Charles Lanier, Treasurer of the Hospital Saturday and Sunday Association, has submitted the following report of the amounts received from the churches, subscription lists, and the boxes deposited at railway stations, ferries, drug-stores, &c.: For general fund, $23,611.22; designated gifts from churches, lodges, and individuals, $15,240.89; designated gifts sent to hospitals direct, $4,357.68; total, $43,209.79. The total expenses to be deducted from the general fund, including charges for advertising, printing, and the manufacture of 700 tin boxes, $1,396.46, will reduce the amount to be distributed among the hospitals to $41,813.33. This amount is nearly double that of last year, and the increase is very encouraging to those who have been interested in the success and permanent establishment of a Hospital Saturday and Sunday.

Plain English and the Metric System.—Dr. S. P. Hubbard, of Taunton, Mass., writes: "In your journal of Jan. 8th is an article from Dr. Eames, highly recommending the metric system as a universal standard of weights and measures for the physician and pharmacist. This all looks well on paper, but the thing cannot be demonstrated. The absurdity of the system has been shown up by able scientific men and the greatest of all; we might as well compel medical men to learn and use the French language, as to compel them to use the metric system in prescriptions and compounding medicines. This brings another thought on the writers for medical journals, viz.: it seems as though they were very desirous of showing they had a smattering knowledge of Greek and French, by their compound words made up of a combination of Greek, Latin, French, Spanish, with a sprinkling of Dutch and Indian thrown in. I think the medical lexicon is quite sufficient to cull medical terms from. It seems to me no mark of science to use such arbitrary terms. The best medical writers use *plain English*, and when they use a medical term it is one that can be found in almost any medical lexicon. *A little learning is a dangerous thing.*"

Genital Malformation.—Dr. H. R. Porter, of Bismarck, D. T., sends the following note: "My attention was called recently to a curious case of malformation of the genital organs, viz.: Maggie ———, child three years old, has the external appearance of a well-formed female, with the exception of a penis where the clitoris should be. Penis is about one inch long, and looks like the penis of an adult, the foreskin being drawn back and remaining so all the time. On separating the labia, no vagina is seen. There is none, but upon close examination a testicle on either side of the penis; they are hardly perceptible to the sight, but can easily be felt under the skin. No sign of any scrotum. The whole thing looks exactly as if an inch had been cut off a man's penis and stuck in between the labia of a little girl's privates. Urine passes from the penis. Parents and child healthy."

Scottish Medical Schools.—Medicine is a very popular study in Scotland, if we may judge from the size of the classes in the medical schools. That at Edinburgh has 600 students; the Glasgow Medical School has 557 students, and the University of Aberdeen has 284 students. In spite of this, however,

according to statistics furnished by the *Medical Press and Circular*, the medical profession is by no means overcrowded, as compared with this country. Thus, in Glasgow, which is such a medical centre, there are 500,000 inhabitants, and only about 300 doctors. The abuses of medical charity, however, limit greatly the number of paying patients. It is calculated that 200,000 persons receive gratuitous medical treatment during the year. Efforts to establish provident dispensaries are to be made.

Dr. John Curwen has been removed from his position as superintendent of the Pennsylvania State Lunatic Asylum, a position he had occupied for thirty years. The cause was his alleged extravagance and unwarrantable assumption of authority. His successor is Dr. J. C. Gerhart, who has been first assistant at the asylum for eleven years.

Quack Advertisement.—The *Detroit Lancet*, referring to quack advertisements in religious journals, says: "Doctors, to a man, are agreed upon it as an evil. The people, including the clergy, are utterly ignorant in the matter. They need light. Who will give it to them?"

The Medical College of the Pacific at its last annual commencement graduated a class of only seven. This was due to the operation of an honest carrying out of the three years' system of study, etc. This school deserves the admiration and indorsement of all who believe in the best class of medical training. Rigid demands for anything will tend to diminish medical classes. The largest schools are those with the most elastic regulations for conferring the degree of M.D. Notoriously what the average student wants is not medical knowledge, but a degree. The medical profession support this vicious principle by patronizing and extolling the schools with the largest classes.—*Detroit Lancet.*

Dr. C. R. Estabrook, Chief of Staff of the Charity Hospital on Blackwell's Island, tendered his resignation yesterday to the Commissioners of Charities and Correction, who accepted it. The resignation will not take effect until March 31st.

The National Government and Contagious Diseases Among Cattle.—A bill has been introduced into the United States Senate, by Mr. Williams, of Kentucky, to prevent the introduction, dissemination, and exportation of diseased cattle. It authorizes an absolute embargo against the exportation of animals from states known to be infected to states free from disease, except under the precautionary regulations of the National Board of Health. It also extends the powers of that board over animal as well as human sanitation, furnishes the board with a veterinary staff, and gives the Federal Courts jurisdiction, and requires them to punish violations of the law. Mr. Williams recently made a speech in favor of the bill, showing the possibility of now exterminating pleuro-pneumonia, and the dangers of allowing it to continue unwatched.

Upon conclusion of his remarks, a select committee of five was appointed on pleuro-pneumonia and other contagious diseases of cattle and other domestic animals.

Another bill on the same subject has been introduced by Mr. Kirkwood.

At a recent meeting of the New York State Agricultural Society, a resolution was passed, calling upon Congress to take measures to stamp out pleuro-pneumonia.

Treatment of Sciatica.—In a clinic given by Dr. Da Costa, ten cases of sciatica were treated with deep hypodermic injections of chloroform daily, near the seat of pain. After a few days, if improvement is not marked, a mixture of ten grains of iodide of potassium with two drachms of ammoniated tincture of guaiac was ordered.

Compound Comminuted Fracture of the Third Toe.—Dr. John N. Upsher, of Richmond, Va., writes: "I was called early on Sunday morning, November 28, 1880, to see the Rev. Mr. ——, who had fallen down a flight of steps leading to the basement of his house, and fractured *the third toe of his right* foot, and receiving some slight contusions besides. His statement was that his wife had called him about 5.30 A.M. to let a dog out of the room. He got up and started (bare-foot) to the front door, but in the dark got too far across the hall, and thus was precipitated down the steps. I found the third toe fractured in its *first phalanx, a little above* the centre of the bone, the bone projecting through the skin (the laceration T-shaped), the flesh drawn forcibly back under the bone, and the internal corner of the bone broken off. The foot was badly bruised as high as the instep, and a space bounded by a line drawn from the internal border of the second toe and the external border of the fourth toe. With some difficulty I succeeded in making extension, and with the flat part of a probe passed under the tissue reduced the fracture. It was retained in place by means of a small pasteboard splint applied on each side of the toe, and a broad splint of binder's-board under the sole of the foot, a small roller being placed under the toes to preserve the convexity. It has been ten days since the injury was sustained; there has been no *suppuration*, the patient very comfortable, and rapidly progressing to complete cure.

"The injury is a most unique one. Many of the best authorities only allude to the injury as liable to occur from the passage of some heavy weight over the toes, and state that the great toe is the one most often injured, and that fractures of the toes, *especially* when *compound, as a rule*, require amputation. The subject of this injury is a young man about thirty-five, with no vice of constitution, in good health, certainly is not a subject of fragilitas ossium, and has never had a broken bone before. Everything goes to show that the toe was broken by the fall, the resistance coming upon the end of the toe, or certainly the extremity of the bone. This is certainly a very rare cause, a very large proportion of authorities stating that fractures in this region occur from a crushing weight *falling upon* the toes. Persons falling from a height, as this patient did, are more likely to sustain fracture of the bones of the leg. 'In 8,667 fractures, 172 involved the bones of the foot, 91 of these were unclassified, and *only* 9 were of the phalanges' ("Agnew's Surgery," vol. i., p. 997).

"It may be urged that I have been too hasty in so soon reporting this case, but repair has progressed to the point where there is no danger whatever of any complication, and where recovery is assured, it being a well-known fact that injuries to the hands and feet, when recovery takes place, advance rapidly to perfect amendment."

The Prodromata of Diphtheria.—Dr. J. R. Brandt, of Robinson, Wis., writes: "I wish to state, for the benefit of the profession, that in examining children in families suffering from diphtheria, I have found in several of those most afflicted, a notable

fall of temperature from one-half degree to one degree, and a very noticeable slowness of pulse, an irregularity in the action of the heart, and a loss of a beat every fifth or ninth, from twelve to thirty-six hours before the child showed any other sign of the disease. Such cases have always proved to be malignant. I am desirous to hear from other members of the profession as to their experience, if any, on these points."

Dislocation of Atlo-axoid Articulation (?).—Dr. Chadwick sends us the history of a case of *dislocation of the atlo-axoid articulation*. The patient, a German, aged thirty-eight, had been thrown over his horse's head while riding on horseback, and fell on his forehead. He was insensible for about ten minutes. Dr. C. was not called to see him till five days after the accident, when he found him cyanotic, with œdema of the lungs, and in an apparently dying condition. The respiration was abdominal; the chin was midway between the sternum and the right shoulder; the posterior part of the neck was swollen and very painful. The immediate danger was relieved by the application of dry cups and mustard to the chest, and the use of digitalis, whiskey, and ammonia internally; catharsis was established by epsom salts. An attempt to reduce the dislocation by the use of as much force as was deemed safe was only partially successful. He was placed in bed, on his right side, with his head high and his shoulders resting only lightly on the bed. During the night he awoke with a start, throwing his weight upon his head, and it slipped back into place with a snap. The recovery was perfect, except that the head was somewhat thrown forward. In conclusion Dr. Chadwick says: "I am aware that the critic will say, Why not reduce the dislocation at once, as it was the cause of the pulmonary œdema? But not seeing the patient till five days after the accident, and not knowing whether the pressure on the cord was due to clot, inflammatory effusion, or bone, and as the man was apparently in a dying condition, I did not care to increase his chances for a necropsy, especially in this city, where malpractice suits are quite fashionable."

Good Whiskey and Bad.—The *Louisville Medical News*, which may be presumed, from its geographical position, to be a high authority on the subject, publishes an interesting article upon good and bad whiskey.

Genuine whiskey, it says, is the product of the distillation of several grains—barley, rye, Indian corn, etc.—either singly or mixed in varied proportions. Originally it contains, besides its alcoholic basis, a mixture of fusel *oil*, which takes its character from the particular grain distilled. This at the outset is rank and perhaps poisonous, but with advancing age it breaks into fragrant ethers, which give flavor and smell to the liquor in which it is contained. No process of art can force the changes in the fusel oil into a much more limited space of time than nature has demanded. In two years whiskey is drinkable, but its better qualities are not developed under five years, and it continues to improve, if kept in wood, so that the air may come in contact with it, for a much longer period. As good whiskey must have a certain age, so it must originally have come from good grain and been distilled in a skilful manner. Age will not make bad whiskey good.

Spurious whiskey is obtained in a number of different ways. The alcoholic basis may be had from the distillation of spoiled or inferior grain, rotten potatoes, and other decayed vegetable matter. Such a product, however, has to undergo manipulation before it can be put on the market. It may be rectified, passed through charcoal, or redistilled.

It comes out as rectified or cologne spirits and is then pure. But it is not whiskey, nor is it drinkable in this state. To change it into an imitation of whiskey, it must be mixed with some of the genuine article, or various compounds are added, some secret, some known to the trade at large, such as burnt sugars, prune-juice, various essences, tobacco, creosote, strychnine, and what not.

These delectable substances may not only change cologne spirits into whiskey but they do actually change it into three-fourths of the French brandies, Holland gins, which flood the markets.

Chemistry is not always able to detect the genuine from the spurious whiskey. Spirits may be chemically pure and yet not drinkable. So that published analyses do not count for much. The best test is the taste and smell. Genuine whiskey diluted with twice or thrice its bulk of cold water gives off a delicate and characteristic perfume. Imitation whiskey similarly treated gives off five or six coarse, nasty smells which struggle with each other for pre-eminence until that of rectified spirits gains the day; and it tastes like what it is, a discordant mixture of ill-assorted flavors.

Kentucky or Bourbon whiskey, which it has been difficult of late to get pure, is, we are told by the *News*, now being manufactured with great care again, and to a larger extent than ever.

Dinner of the Alumni Association of the Medical Department of the University of the City of New York.—The tenth annual dinner of this association was held on Tuesday evening, January 25th, at Delmonico's. The occasion was an exceedingly enjoyable one, the attendance was large, menu unexceptional, and the post-prandial speeches numerous, entertaining, and brilliant. A band in the gallery of Delmonico's large hall discoursed choice selections during the evening. The table was tastefully decorated, and the walls were hung with portraits of the Chancellor, of the late Professors C. A. Budd, Valentine Mott, and Martyn Paine. The President of the association, Professor D. B. St. John Roosa, occupied the chair, and made a happy and humorous address, after which he introduced the speakers of the evening in his usual felicitous style. The following were the toasts, with their respective respondents: "The University of the City of New York," by the Rev. Dr. Howard Crosby; "Our Alumni," by Dr. A. E. Macdonald; "The Medical Department," by Professor J. W. S. Arnold; "Sister Colleges," by Professor J. M. Bryant; "The Bar," by R. O'Gorman; "The Press," by W. Winter, who recited a poem entitled "Hesperides;" and "Woman," by Professor Montrose A. Pallen. George Fawcett Rowe gave a recitation entitled "The Quid."

Subjoined are the names of the officers announced as elected to serve during the year 1881:

President, Theodore R. Varick; *Vice-Presidents*, William A. Hammond, John R. Dickson, J. W. S. Gouley, W. E. Ford, Stephen J. Clark, A. E. Macdonald; *Secretary*, Frederick R. S. Drake; *Treasurer*, C. Dixon Varley; *Executive Committee*, F. Le Roy Satterlee, Edward L. Pardee, Andrew Otterson, R. A. Witthaus, Newton M. Shaffer, J. H. Hobart Burge, H. B. Conrad, R. A. Murray, B. D. Carpenter, Lewis Fisher, George K. Smith, and F. D. Weisse.

Original Lectures.

ON THE BENIGNITY OF SYPHILIS:

BEING A STUDY OF THE DISEASE, ESPECIALLY AS IT AFFECTS SEAMEN.

AN ESSAY TO WHICH WAS AWARDED THE ANNUAL PRIZE OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, FOR THE YEAR 1880.

By CHARLES L. DANA, A.M., M.D.,

PROFESSOR OF PHYSIOLOGY IN THE WOMAN'S MEDICAL COLLEGE, NEW YORK.

The question of the actual amount of harm which the syphilis of the present day inflicts upon the human organism is one which is by no means exactly settled. It is a question, moreover, of interest to medical science, and of importance to the sociologist and legislator. It is known that the disease runs its course with varying degrees of severity; so much so that a classification has been based upon the fact. It is asserted to affect certain nations mildly, and that the races which it reaches for the first time suffer with especial severity from its ravages. It is believed to affect different persons with different degrees of severity, according to the condition of their health, their idiosyncracies and personal habits, or, possibly, according to whether they have received a hereditary protective influence. It is known that the disease will sometimes run its course and apparently exhaust itself, even when the person receives no treatment. It is furthermore asserted, that the disease is not so virulent now as it was during the century when it first conspicuously appeared. And it is asserted, also, with confidence, that, especially during the present century, its severity has abated.

It is in regard to this last assertion, and in regard to the question of what is the exact amount of injury which syphilis inflicts upon the human constitution, that the accompanying statistics are given.

While assistant surgeon in the U. S. Marine Hospital Service, being stationed in New York, I had an opportunity to see and get the personal history of nearly 2,500 seamen. It was not long before I was struck with the fact that despite the extraordinary frequency of a past history of venereal sore, very few presented any evidences of the serious ravages of syphilis. Determined to make more exact inquiries, I questioned every applicant for medical relief at the office for a considerable period of time. Notes were made of his age, nationality, past history, and present condition. These histories, for the sake of easier study, have been put into tabular form and accompany the present paper.

The sailor, as a rule, does not have any hesitation in saying that he has had a venereal disease, if such is the case. Where all venereal disease is denied, therefore, I have taken the statement of the case as true. Still, there was, no doubt, a certain amount of deception, especially among native Americans; therefore the per cent. of venereal disease is rather underestimated than otherwise.

With regard to the diagnosis of what the affection really was in the past, whether a chancroid or chancre, I have acted on the following plan: If the patient stated that he had had a sore some time previously, with no suppurating bubo, and with a partial history of secondary syphilis, the case was put down as "hard chancre," with an interrogation mark after it. If, with a history of a sore, there was given a good history of secondary symptoms, the case was marked as "hard chancre." If there had been a sore with suppurating buboes, and no subsequent symptoms, the case was marked "soft chancre." If, with the history of a sore and suppurating buboes, there was an indefinite history of secondary syphilis, the case was marked "soft chancre," with an interrogation mark after it. Such was the general rule. But in addition to this, there were often other evidences, such as statements of previous attending physicians, the length of time which the sore had lasted, its period of incubation, etc., all of which often helped in making the diagnosis of the previous disease more certain. It might be said that some of the alleged chancres were only abrasions or herpetic eruptions. This possibility was borne in mind when getting the histories. Besides, non-specific sores are rare among seamen, as the Marine Hospital reports show. So that the tables closely approximate accuracy.

A synopsis of the facts furnished by a study of the cases is here given: total number of cases, 378; total number of cases having or having had venereal disease in some form, 279; per cent. of cases having or having had venereal disease in some form, 72.81; number of persons with a past or present history of syphilis, 149; number of persons with a *past* history of syphilis only, 106; cases presenting secondary symptoms, 31; cases presenting *hard chancre*,* 12; per cent. on whole number of cases having a *past* history of syphilis only, 28.09; persons presenting or having had soft chancre, 123; persons presenting *soft chancre*, 12; per cent. of syphilis, past and present, on whole number of cases, 37.

Cases of gonorrhœa, past and present, 166; cases of gonorrhœa, present, 23; per cent. of gonorrhœa, 43.93; per cent. of persons having or having had hard chancre, 39.18; per cent. of persons having or having had *soft chancre*, 26.19; per cent. of persons having or having had chancre (hard or soft or both), 65.60.

Estimated total number of American seamen, 170,000; estimated number having or having had syphilis, 40,000 to 50,000; ratio of hard to soft chancres, 12 to 12; ratio of histories of hard chancre to those of soft, 149 to 123; ratio of gonorrhœa to hard or to soft chancres, 23 to 12.

It is believed that the above figures represent very fairly the condition of things as regards the prevalence of venereal disease among the whole body of seamen. The histories specially obtained corresponded closely with those incidentally noted before and after the investigation. The inquiries were discontinued indeed, because of the monotonous sameness of the replies. The sailors, it is to be remembered, were not especially of New York. The sailor has no home; and the prevalence of venereal disease among the seamen of the great lakes and rivers of the west is even greater in some parts than it is in the east. This is shown by the statistical tables of the Surgeon-General U. S. Marine Hospital Service,† and the fact is confirmed by the medical officers of the service with whom I have conversed.

* The terms hard and soft chancre are used in preference to "initial lesion of syphilis" and "chancroid," because they are more convenient, are well understood, and are in accordance with the nomenclature of the British Medical Association.

† See table, p. 142.

It will be seen from the figures given above, that of the 378 patients treated, 279 (about 73 per cent.) had had, or still presented, some form of venereal disease. The number of cases presenting hard and soft chancres was equal, there being 12 of each. The number of cases giving a partly probable but mostly certain history of syphilis was 149, while that of soft chancre was 123. This represents an excess of syphilis over chancroid which is rather unusual, but the fact is not to be doubted. It is known that the ratio between hard and soft chancres varies in different years and under different conditions. This has been illustrated at the Hôpital du Midi, where the ratio has varied from 1 to 8, to 4 to 1. It is asserted, though on no strong statistical evidence, that chancroid is more frequent than hard chancre among the lowest classes. However this may be, I am convinced that there are often more cases of syphilis than of chancroid among seamen. In reported tables of the U. S. Marine Hospital Service, 1880, the proportion of hard to soft chancres is about as 1 to 3. The proportion of soft chancres to primary and secondary syphilis shows syphilis to be a little in excess. I refer to this point in order not to be accused of unwittingly exaggerating the amount of syphilis among the men examined.

Now as regards the effect of syphilis upon these men. Notes were made of their physical condition when presenting themselves at the office. In only four cases was the condition really very bad. In one of these the patient had lost an eye from a syphilitic iritis. Another was crippled with rheumatism, and he had had severe spinal pains and a muscular atrophy previously, symptoms which had been attributed to syphilis. The other two were anæmic and weak, but were not at all seriously run down. Some of the remaining cases had obstinate rheumatic pains, some showed anæmia; there was an occasional obstinate leg ulcer or painful node.

There were 106 who presented themselves with a previous history of syphilis, but who had no primary lesions or secondary symptoms at the time—except in some cases rheumatism, a disease which is the bane of the sailor, whether syphilitic or not. There were none, either in the 378 cases reported, or in the 2,000 others seen by myself, who were suffering from bad necroses, or tumors. Nor were there any cases of malignant or "galloping" syphilis. I have never heard of this latter form of the disease among seamen. The sailor himself, as a rule, does not regard the chancre as meaning very much, and is not disturbed by the idea that there are any terrible sequences to it. If asked whether he has ever had "venereal," he may say "No," at first, and then add: "Nothing but a chancre a good while ago; but I got all over that." Now if the chancre did carry serious troubles in its wake, the fact would be known and appreciated. For, though the average American seaman (being often a foreigner) is a somewhat dull and insensible being, yet the crew of a vessel rarely fail to discuss their physical condition among themselves, and often to interchange advice or remedies. The terrors of "secondary" or "tertiary" would be known if they existed. But it is the *sore*, or the *bubo*, that annoys them. And I believe it would be found that suppurating buboes, as a rule, lay the sailor up longer than "primary," "secondary," or "tertiary" symptoms do altogether.

The course of the disease is not often much modified by any treatment that he gets. The sailor will generally go to the doctor to be treated for his chancre. As soon as this is well, or is improving, he ships again. Then, if secondary symptoms break out while on ship-board, he gets from the captain an inevitable dose of salts. This may be followed by a little potash; and occasionally the captain salivates him—to prevent the accusation of indifference. But any regular or intelligent treatment he does not receive until he gets back to port. Then he will perhaps go under an antisyphilitic treatment for a short time till he feels better, when he ships again. But even this amount of treatment is not always obtained. There were 106 persons, as before stated, out of the 378, who presented themselves for the most part for other troubles than the syphilis of which they gave a history. This gives a per cent. of 28.09 upon the whole number. It would be a low estimate to suppose that this represented the per cent. of syphilis among seamen generally. As the total number of American seamen is about 170,000, the number who have had syphilis, or (to make the estimate free from any possible exaggeration) the number who have it or have had it, would be from 40,000 to 50,000. Now the total number of syphilitic cases treated in all the marine hospitals during a year is considerably less than a thousand. These facts tend to confirm the statement that seamen do not as a rule get any regular or thorough treatment for the secondary symptoms of syphilis.

In reaching this conclusion it is to be remembered that many sailors get some treatment outside the Marine Hospital Service. But they never have money enough to pay for such outside medical care very long.

In regard now to the effect of syphilis upon the mortality of seamen. I present, first, a table showing the total number of cases of diseases treated in the different marine hospital districts during 1878 and 1879, the number of cases of secondary syphilis treated, and the number of deaths from the same.

Districts.	Total number of cases.		Number of cases of secondary syphilis. †		Deaths from secondary syphilis.	
	1877-78.	1878-79.	1877-78.	1878-79.	1877-78.	1878-79.
North Atlantic..	1,195	1,168	30	49	0	0
Mid. Atlantic*..	1,660	1,779	99	103	1	1
South Atlantic..	897	1,540	69	59	3	1
Gulf.....	1,649	1,839	64	63	1	0
Ohio.....	681	1,129	125	100	0	0
Great Lakes...	703	1,573	73	104	1	0
Mississippi....	1,504	1,491	126	96	1	3
Pacific...	1,014	1,688	37	58	0	0
Total.....	9,304	11,412	617	652	7	5

It will be seen that the proportion of syphilis in the District of Ohio is greater than it is in the Middle Atlantic District, which includes New York; also, that the mortality in the former district is *nil*.

It is undoubtedly the case that some of the alleged deaths from secondary syphilis were due to complications, in causing which syphilis may have played but a small share.

Such error is perhaps balanced by deaths produced by syphilis indirectly.

But furthermore, the total number of cases given represents only those treated in hospital. A little less than half as many more were treated as out-

* This district includes New York.

† Tertiary syphilis is not recognized as a separate form by the Marine Hospital Service, whose nomenclature of diseases is modelled after that of the British Medical Association.

patients, and among these there were no deaths from syphilis reported. The ratio of deaths to the total number of cases of secondary syphilis treated, is, therefore, much less than appears from the table. It may be safely estimated that the ratio of mortality among the 20,000 seamen treated in 1878–79, is not over one death to 800 cases of secondary syphilis. Even this is a much larger estimate than would be made from the statistics of Dr. King, given later.

Bearing upon the case is given another table, compiled from the annual reports of the Marine Hospital Service:

Year.	Number of cases.	Total deaths.	Deaths from syphilis.
1873–74	11,832	646	5
1874–75	12,939	462	6
1875–76	13,303	434	7
1876–77	15,175	434	7
1877–78	18,223	324	7
1878–79	20,922	387	5
Total	92,394	2,687	37

Among 20,000 seamen treated in 1878–79, the per cent. of mortality from syphilis was one-fortieth of one per cent.

Through the kindness of Dr. C. Henry King, Physician-in-Chief to the Seamen's Retreat Hospital, Staten Island, further statistics as to the mortality from syphilis have been obtained. It will be seen that in five years no deaths whatever were attributed to syphilis in a hospital devoted exclusively to the care of seamen: *

Year.	Total number of cases.	Number of cases of syphilis.	Deaths from syphilis.
1873	1,593	220	0
1875	692	94	0
1877	728	116	0
1878	991	179	0
1879	1,131	218	0
Total	4,916	727	0

But, in addition to the above facts, pointing to the mildness of the syphilitic virus, is another. Sailors live, in large part, under bad hygienic conditions. Their life ashore is a succession of "sprees," from which they recuperate between times in crowded, dirty, and ill-ventilated boarding-houses. When on ship-board their quarters are close, their food poor; they are often insufficiently clothed, and they are constantly exposed to all kinds of weather, so that rheumatism is extremely common among them. For these and other reasons, the physical condition of the sailor is at as low an ebb, perhaps, as that of any class of workmen.† Yet in spite of this, syphilis does not attack them malignantly.

As this essay assumes to be only a contribution to the subject in hand, and not a comprehensive survey of it, no historical details or further comparison of the views of others will be given.

It would be natural, however, to seek an explanation of this apparent mildness of syphilis in seamen. It might be attributed to national peculiarity, only the American sailor is of *all* nationalities. Of the 378 cases recorded, there were: Americans, 183; Scandinavians, Finns, Danes, and Russians, 94; Irish, 51; Germans, 26; English, 13; French and Italians, 7; West Indians, 4.

The Danes, Finns, Swedes, and Norwegians make up a larger part of our merchant service than would be inferred from the above figures. They make up the majority, often, of the crews of our sailing-vessels; while the Irish go almost altogether on steam-vessels. Now the Irish are certainly more severely affected by syphilis than some of the other nationalities. On the other hand, the theory which has been applied to the Portuguese may do for the nations on the north coast of Europe. This theory is, that a race, after generations of exposure, becomes at last too barren a pasture for the syphilitic poison to flourish in. A large proportion of the populations of Scandinavia, Denmark, and Finland has always followed the sea and been exposed to the accidents of that kind of life. It might be very plausibly argued, that as succeeding generations came on, an immunity was secured.

Many believe that the mildness of syphilis is due, in a great many cases, to the improved treatment it now receives. But the life of the sailor does not permit of his regularly getting such treatment.

The conclusions then are:

First.—That syphilis, as a rule, runs a very mild course indeed, among American seamen, and physically incapacitates them less than either soft chancre or gonorrhœa with their complications and sequelæ.

Second.—That it runs this course, often without regular treatment, and almost always in spite of irregular living and unhygienic surroundings. These two conclusions, it may be added, tend to confirm the views of those who believe

(*a*) that syphilis is curable, and, furthermore,

(*b*) that it very often has a tendency to spontaneous cure:

(*c*) that this present benignity of the syphilitic poison is due in part to treatment, in part to a gradual change, either in the character of the poison itself, or in the organism it feeds on, or both.

If any credence can be put in the recent experiments of Koch, Buchner, Toussaint, Pasteur, Greenfield, and others, then we may believe that the characters of the germs of even specific diseases (*e.g.*, chicken-cholera, anthrax) can be modified and even totally changed by artificial manipulations and cultivation. And, in the light of the assertions made by these experimenters, it is no mystery that the syphilitic virus should be modified in its characters. Not much can be inferred, however, from pathological theories regarding acute diseases.

The question of benignity or virulence of syphilis, as it attacks other classes than sailors, is left untouched, and the term "benign" is used only as indicating that the disease is not malignant nor fatal, nor, as a rule, severe.

I would certainly not have it thought that I am advocating the view that syphilis, in general, is an innocent disease. It is only comparatively speaking that the term benign is used.

And furthermore, if it does affect the sailor with comparative mildness, it is, for all that, sufficiently bad and disabling. And this, with the other venereal diseases, and his mode of life, makes his physical condition, as has been said, a very poor one. Nearly

* I also append certain statistics, bearing on the mortality from syphilis, compiled by Dr. J. Birkbeck Nevins, of London, from the Registrar General's return of births and deaths in England from 1848 to 1872 (vide appendix).

† See Annual Reports Seamen's Retreat Hospital. By C. Henry King, M.D., 1875 et seq.

three-fourths of American seamen have or have had some form of venereal disease. In every form the man is disabled for the present and runs a risk for the future. It may be pertinent, therefore, in conclusion, to inquire whether anything can be done to prevent this vast amount of infection and disease.

There are several directions in which philanthropic effort might be directed.

First.—The improvement of his "environment," of his social and sanitary surroundings when on shore; the getting him out of the clutches of boarding-house keepers and others who fill him with bad liquor, entice him into brothels and rob him of his money. If his social condition were bettered, his moral improvement would surely follow or go with it. Something is being done in this direction.

Second.—The regulation of prostitution. That this would benefit him to some extent there can be no doubt. But the system of regulation would have to be comprehensive and very efficiently carried out. It would have to be applied to the whole municipality, and its adoption involves the general question of the regulation of prostitution, which this is not the place to discuss.

Marriage, so far as it is possible, is a help to the sailor. Of the 378 men examined, there were not thirty who were married. The sailor is a celibate. But among these 351 celibates there were 272 cases of venereal disease. On the other hand, of the 27 married seamen, 14 never had had any venereal disease, and 21 never had any during the period of their marriage. Of course, matrimony is often impracticable or unwise, but celibacy is also more frequent than it need be.

As the sailor's sanitary, social, and moral condition improves, the possibility of and desire for domestic life will increase, and will do its share to improve his physical condition.

APPENDIX.

There are some interesting facts, obtained from the accompanying record of cases, which do not bear directly upon the subject of the essay. They do relate to it indirectly, however, and are therefore inserted here.

It is curious, not to say startling, to learn the number of times which the same person has had gonorrhœa, syphilis, or chancroid, one or all. In 149 men there were histories of infection with chancre 156 times; in 91 men who had had chancroids there were histories of 121 infections; in 166 men who had had gonorrhœa there were histories of 284 attacks.

As illustrations: E. Hayes, aged thirty years, native of Sweden, had had gonorrhœa 5 times; chancre, 1. Present condition good.

Jas. Bell, aged thirty-six years, Ireland; gonorrhœa, 3; chancres,* 7. Present condition noted as good.

Patrick Downey, aged thirty-five years, New York; gonorrhœa, 4; chancres,* 4. Present condition good.

Jas. King, aged thirty-five years, United States; gonorrhœa, 4; chancres,* 4.

Chas. McCannon, aged fifty years, Ireland; gonorrhœa, 8; chancres,* 4. Present condition good.

Wm. Mosher, aged thirty-eight years, New York; gonorrhœa, 12; chancres, 3.

Michael Malloy, aged forty-two years, New York; gonorrhœa, 14; chancres, 2.

None of the above cases showed a seriously impaired constitution.

* Hard and soft.

There were seven cases (Nos. 24, 98, 167, 175, 236, 328, 346) in which the histories pointed to a second infection of syphilis. In all except the last two, however, there was more or less element of doubt. Nos. 328 and 346 gave a good history of a second infection.

MORTALITY FROM SYPHILIS IN ENGLAND AND WALES.

Only 1 infant dies yearly under one year old from hereditary syphilis in a population of 24,500 persons.

Only 1 child dies yearly between one and five years old from hereditary syphilis in 273,334 persons.

Only 1 person dies yearly from syphilis between fifteen and fifty-five years of age in a population of 78,000 persons.

The total deaths from every cause are 448,829 yearly.

The total deaths from syphilis at every age are 1,201 yearly.

The deaths from syphilis, both hereditary and self-contracted, are therefore only 1 in 374 deaths.

So far for the *actual mortality* from this disease.

When *compared with* that from *other diseases* the following is the result: There are 25 causes of death which are so *frequent* and *important* that they occupy 419 pages in the supplement to the Thirty-fifth Annual Report of the Registrar-General—but *syphilis is not once alluded to.* There are 20 diseases which are supposed to be so *preventable* that they are specified in the form supplied by the government to every "Medical Officer of Health" in England that he may inform the government of their prevalence—*but syphilis is not included among them.*

The published reports from 188 of these "Medical Officers of Health" have been obtained, and *only two of them* mention syphilis at all in their reports. (Evidence Select Committee, 2-350.)

When compared with some other diseases syphilis shows the following mortality on the average of 25 years (omitting decimals):

Syphilis.		*Other diseases.*	
Syphilis	6	"Thrush"	7
Syphilis	1	Rheumatism	3
Syphilis	1	Measles	10
Syphilis	1	Whooping-cough	11
Syphilis	1	Scarlet fever	20

There are 60 diseases tabulated in the order of their fatality by the Registrar-General.

In 1868 syphilis stood 42d in the list—Thirty-first Annual Report, p. 227.

In 1872 syphilis stood 45th in the list—Thirty-fifth Annual Report, p. 244.

On the average of 25 years it stood 53d in the list, computed from tables, pp. 138 and 149.

From a return to the House of Commons of all the deaths from syphilis in the *workhouses* in England and Wales during the year 1875, it appears that the deaths from syphilis, at all ages, in the workhouses—that is, among the lowest classes of society—are only 8 per million inhabitants. And the deaths from syphilis, at all ages, in the workhouses even of Middlesex, Surrey, and London, are only 10 per million inhabitants. In the case of workhouse deaths there is no inducement to conceal the real cause, and the above, therefore, represents the true mortality, if any returns are to be accepted as true; and the proportion of deaths is even lower than that recorded for the general public by the Registrar-General.

Tabular Record of the Histories of Three Hundred and Seventy-eight Seamen—*March to June*, 1880.

O = no venereal; X = disease present or past.

Names.	Age.	Condition.	Nativity.	Whether they had: Gonorrhœa.	No venereal.	Chancre, hard or soft.	Number times the person has had gonorrhœa.	Chancre with suppurating bubo.	Chancre, with indolent bubo.	Chancre, without noticeable bubo.	Soft chancre.	Hard chancre.	How long ago.	Previous treatment, if any.	Remarks. Present condition as regards general health.
1. Frank S	27		Virginia		O										Muscular rheumatism.
2. C. A	37		New York			X				1		1	1872		Otitis media; condition good; some secondary symptoms followed, 1872.
3. C. L	22		Maine	X		X	3			1	1?				Gleet.
4. W. E	36		West Indies	X			1								Gastralgia.
5. James H	22		Ireland												Sciatica.
6. J. B	38	Unmarried			O										Eczema of hand.
7. A. T. K	24		New York	X		X	1			1	1?				Condition good.
8. S. W	25		New Jersey			X			1			1	1877		Chancre, followed by secondary; present condition good.
9. J. E	30		Finland			X				1	1?		1877		Rheumatism, chronic.
10. M. McM	20	Married	United States		O										Ague.
11. A. J	28		New Jersey		O										Rheumatism.
12. S. McC	40		New York			X				1		1?	1868		Since then has been tolerably well, but has had, and has now, rheumatism.
13. —— ——	40	Married (unmarried when he had venereal).	Ireland	X		X	6	1			1		1865		Healthy; pleurodynia.
14. William J	23	Unmarried	Maine	X			1								
15. P. M	26	Unmarried	Ireland			X	1		1			1?	1877		Been well except for slight rheumatism; now has orchitis.
16. Charles W	35		New York	X		X	1			1			1860		Well until six months ago, when he developed heart disease, hyperæmia, and aortic regurgitation.
17. J. W. C	21		New York	X		X	2			2	1	1?			Good; gonorrhœa now.
18. Nils N	22		Norway	X											Pityriasis versicolor.
19. Andrew L	32		Norway		O										
20. C. V	34		United States	X		X	2			1		1	1878		Rheumatism had, subacute, with atrophy formerly.
21. R. S	45	Married since	New York			X		1					1865		Well; sinus in arm.
22. I. A	26		Finland	X		X	1			1			1872		Good; rheumatism and cough.

Progress of Medical Science.

BROWN-SÉQUARD'S EXPERIMENTS ON THE APPLICATION OF CHLOROFORM TO THE SKIN.—Brown-Séquard has given notice that he intends to publish some recent experiments on the cutaneous application of chloroform. Meanwhile we learn something of the nature of the results he has obtained from communications both by himself (*Gaz. méd. de Paris*, December 4, 1880) and his assistant, Henocque (*Gaz. Hebdom.*, November 10, 1880). It appears that the application of the anæsthetic to the skin rapidly produces well-marked changes in the organic functions of nerves and muscles. Moreover, these modifications are of constant occurrence, and have not been hitherto observed or described. He was accidentally led to undertake these investigations by noticing the peculiar effect produced upon a guinea-pig by drops of chloroform inadvertently falling upon the region between the shoulder and neck of the animal. The effect alluded to was the almost instantaneous production of an epileptic attack. When chloroform was poured on the necks of other guinea-pigs profound anæsthesia resulted. Similar results were obtained with dogs, cats, and rabbits, and, although certain differences were noticed, the prime fact of the production of profound anæsthesia remained the same. The animals experimented upon gradually recovered consciousness and activity. In some instances there remained a condition of cutaneous hyperæsthesia, or inflammation occurred if the experiments were repeated and much chloroform employed. Sometimes the experiments proved fatal.

The stimulation of nerves and muscles showed these organs to have become unusually excitable. Brown-Séquard also observed a persistence of this irritability after death, in a considerably higher degree than is commonly seen in healthy animals killed by opening the chest. In certain cases it was found that the phrenic nerve on the side opposite the one to which the chloroform was applied, showed a diminution, or even the complete absence of its galvanic irritability. The author thinks he has for the first time observed the loss of muscular excitability as the result of remote irritation. The rectal injection of chloroform, and its absorption by the lungs, neither produces similar phenomena nor yet prevents their occurrence. Brown-Séquard has classed all these phenomena in a group designated phenomena of inhibition.

At a recent meeting of the Biological Society of Paris, he also explained that these inhibitory effects appear in guinea-pigs on which venesection of the cervical portion of the spinal cord had been practised. But they only appeared provided the chloroform were applied on the same side with the spinal lesion, and behind its site. If applied on the other side, the chloroform remained inert. Other experiments upon frogs and guinea-pigs have made it clear that the cutaneous action of chloroform takes place through the irritation of the nerves of the skin. In certain other experiments it was ascertained that the cutaneous application of chloroform, as well as its action on the broncho-pulmonary surface and other parts, brought about an inhibition of reflex symptoms, and other manifestations of cerebro-spinal activity. Moreover, this took place even if the circulation was completely suppressed. The effects were the same as if the anæsthetic had been absorbed

by the blood and carried to the nerve-centres. Hence the author concludes that the chloroformic irritation of nerve-terminations in the skin and mucous membranes may lead to effects which resemble those due to the inhalation of the anæsthetic, as well as others which have been observed in cases where large quantities of chloroform were taken by the mouth.

Orange-Colored Pus.—The occurrence of a yellowish or orange discoloration of purulent discharges is known to be rare, and its pathological significance is a point not yet definitely settled. Prof. Verneuil (*Archives générales de médecine*, December, 1880) has just published a somewhat lengthy contribution to our knowledge of the subject, from which the following is gathered: Delore, of Lyons, in 1854, first called attention to the matter in an interesting inaugural thesis on pus. This author, however, was able to collect only eight cases of orange pus, although he expressed an opinion that such a complication was not very rare. He thought that it was a symptom of grave import, denoting either the actual presence of pyæmia, or else its gradual approach. The eight recorded instances proved fatal without exception. In 1855 Zeis (*Bull. Soc. biol.*, 1855, p. 148) read a paper on the subject, which embodied the results of his studies regarding the nature and composition of the questionable pus. Verneuil himself was able to confirm the observations of Delore, in 1870 and 1871, for at that time he saw such cases, and almost without exception the patients died. In addition he found, that orange pus was apt to appear in subjects having a constitution vitiated by some systemic condition, such as alcoholism, diabetes, phosphaturia, etc. In a case of depraved health, following the abuse of morphine, the symptom was also seen, and likewise proved fatal.

According to Robin, whose histo-chemical researches are very complete, the orange color is due to the presence of large quantities of hematine or the formation of crystals of hematoidine. Besides these elements, an ochre-colored amorphous substance, representing the molecular detritus of anatomical structures mingled with destroyed red blood-corpuscles, is generally present. M. Nepven has also made an examination of the questionable pus, and he holds the same opinion concerning its chemical nature. The investigations of Broca led him to discredit any notion of a possibly parasitic nature of the orange coloration.

Verneuil never saw this symptom before the third or fourth day, and ordinarily it was a temporary affair, persisting only in certain very grave cases. He found, moreover, that there existed certain local predispositions to its development, such as exposed fractures, contused wounds, superficial gangrene. But this alone would not suffice to bring on the phenomenon under consideration, otherwise its greater frequency of occurrence would have more generally attracted the attention of surgeons. When, however, such conditions were associated with constitutional disturbances, then orange pus was likely to be seen. Among the already observed dyscrasias, he mentioned morphinism, alcoholism, diabetes, and phosphaturia, but in malarial intoxications, renal or hepatic diseases, the same thing was liable to occur. Thus it appeared that a double order of pathological states was necessary, or, at any rate, favorable to the production of the symptom. A satisfactory explanation of the proximate cause could not yet be given.

Although Verneuil saw many patients with orange suppuration die from pyæmia, he was, nevertheless, inclined to regard the two in the relation of accidental coincidence rather than causal connection. Notwithstanding all this, the appearance of orange pus should come as a warning to the surgeon, since it probably indicated constitutional disturbance. The sum of the whole matter was that in such cases treatment was to be conducted according to general indications.

The Peritoneal Transfusion of Blood by Ponfick's Method.—The well-known experiments of Ponfick have conclusively shown that blood may be allowed to flow into the abdominal cavity without causing unpleasant symptoms, and that it will be absorbed from the peritoneal surface and thus enter the system. In the few recorded instances, where this method has been tested in the light of a life-saving or life-prolonging measure in the human being, the actual results have justified or even exceeded the anticipations of the operators. Of course the immediate benefits of vascular transfusion are sufficiently evident from the fact of its more rapid action, so that in acute cases the older method will probably not be supplanted by the more recent one. Yet, even here the danger may possibly be tided over by invoking the aid of auto-transfusion, and then, in the lull after the momentary crisis, proceeding to perform peritoneal transfusion. Dr. Kaezorowski (*Deut. med. Wochenschrift*, November 13, 1880) has reported five new cases, which are well calculated to illustrate the good results obtainable by abdominal transfusion. In one of the five which he gives, some tenderness at the sight of injection was noticeable for several days after the operation. But in the other four it was exceedingly well borne, and in all instances a marked improvement of the patient's condition was observed.

Such encouraging results will not fail to stimulate the profession to future trials. One very apparent advantage of the new method is its great simplicity. For the performance of this simple manipulation there is required neither surgical skill nor a special apparatus. Any ordinary appliance for piercing the abdominal walls, and injecting a sufficient amount of fluid, will answer for the purpose in hand. Of course we would not be understood as indiscriminately advocating the adoption of this method, nor would we wish to see intravascular transfusion banished from grace by this new-comer. Nevertheless, the latter may be tried in what appear to be suitable cases, when its proper sphere of utility will doubtless soon be discovered. From a consideration of the cases hitherto reported it would appear to be specially indicated in those prolonged febrile affections, where cardiac failure from insufficient blood supply is a dreaded consummation. Intractable chronic anæmia seems to furnish another indication for its employment. And certainly if future experience should continue to bear testimony to the innocuousness of the measure, the conditions justifying the performance of the operation will speedily increase in number. Finally, as regards the technique of the manipulation, it may be stated, that a curved trocar was plunged into the abdominal cavity by the linea alba, and the defibrinated blood (on the average about one pound and a third) allowed to flow in by means of a rubber tube connected with a glass funnel.

"Creamery Butterine" is the name of a new artificial butter. It is made by mixing ordinary butter with other fats, and is much more palatable than oleomargarine. It is difficult to distinguish it from real butter.—*The Analyst.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 5, 1881.

MYOPIA IN THE SCHOOLS OF DIFFERENT NATIONS.

THERE have been several contributions of late upon the subject of ocular hygiene in schools.* These have been accompanied with numerous statistics which cannot fail to excite much attention.

A most interesting side to the facts that have been thus given is that which shows the variations in the per cent. of myopes among different nations. So far as investigations have gone they show that myopia scarcely prevails at all among uncultivated people. Dr. Macnamara states that he never met a case of short-sightedness among the Bengalese, and that the disease scarcely exists among the lower classes of India. Among several hundred colored school-children examined by Dr. Callan, of New York, only 3 per cent. of the pupils were myopic.

Such results as these are perhaps what might be expected. But it does not follow that myopia increases in proportion to the intelligence and education of a people, for the English have very little of it despite the fact that so large a proportion of their schools are in dark and smoky cities.

There seems to be very little myopia among the Irish; there certainly is very little among those who have emigrated to this country.

The Americans rank very near the English and Irish in their freedom from myopia, though it exists largely in our cities. In the schools of Detroit, according to Dr. Lundy, among the pupils of seven or eight years of age—pupils who had attended school for one or two years—there was no myopia whatever. In the highest grade of ten high-schools it was only 12 per cent. In the highest grade of the Cincinnati schools, the per cent. is 16, while in the New York College and in the Brooklyn Polytechnic it rises to 30 or 40 per cent.

These last high figures are undoubtedly due, in part, to racial influences, for it has been found that in the same schools and same classes the per cent. of myopia among Germans is 24, while that among Americans is 19, and that among Irish only 14 per cent.

Russia is not a nation that has ever been noted for its educational work, or that has been characterized by any widespread cultivation or scholarship, yet there is a high per cent. of myopia in its city schools. This per cent. runs from 13.6 in the preparatory classes to 41.3 per cent. in the highest classes.

It is in Switzerland and Germany that the most alarming amount of myopia has been found. And, in addition to the large percentage of myopes, there is the fact that the percentage increases with great rapidity in ascending from the low to the higher grades in the schools. This is a peculiarity in which, so far as statistics show, the German and Swiss schools differ from the Russian, American, and English. Thus, in Lucerne, among the school-children seven years old there was no myopia; among the students who had reached their majority the per cent. was 61.5. In Breslau the percentages ranged from 0.4 per cent. among first half-year scholars, to 63.3 per cent. among those in the highest classes.

Drs. Loring and Derby found that in New York the range was from 3.5 per cent. in the youngest pupils to 26.78 per cent. in the oldest. The range of percentage in the St. Petersburg schools we have already given.

With regard to these facts of racial difference in the prevalence of myopia, it is impossible as yet to assign the exact cause. The Germans have the greatest application, and the worst print and script of all the European nations. On the other hand, the English are the best printers in the world, and they unite much vigorous out-door exercise with their study. The excessively rapid development of myopia among German school-children shows that they are subjected to very active exciting causes. Dr. Cohn condemns the German letters severely, and recommends the use of short-hand as a substitute for the ordinary script. He asserts that much writing causes a great strain on the eyes, which induces myopia.

There is no positive evidence that the forcing an education upon a previously uncultured people induces an excessive amount of myopia. On the other hand, the Germans have a high per cent. even when under the best hygienic conditions. We are inclined, therefore, to assign a very important place to hereditary predisposition in the production of myopia.

But, whatever the causes, there is certainly something very pitiable in the fact that out of ten children who, at the age of seven, have normal eyes, six at the age of twenty-one will have myopia. And

* Address of Prof. H. Cohn, at Danzig. St. Petersburgher med. Wochenschrift, No. 38.

The Function of Vision, by Dr. Giraud-Teulon. London: Bailliere, Tyndall & Cox. 1880.

Light in the Public Schools, by C. J. Lundy, M.D. Report of Michigan State Board of Health.

myopia, it should be remembered, means more than simply a defect in the range of vision. There is, in a large proportion of cases, a loss of visual acuity also.

Dr. Giraud-Teulon has shown that in myopiæ, ranging between 0 and $\frac{1}{12}$, 1.25 per cent. are, for industrial purposes, "lost eyes." In myopia ranging between $\frac{1}{4}$ and $\frac{1}{6}$, there will be per hundred cases 4.34 of "lost eyes." This ratio increases with the increase in the myopia, until, in cases where the defect exceeds $\frac{1}{2}$, the per cent. of those having no useful vision is 28.48.

Such nations as Switzerland and Germany, therefore, may well look upon the progressive increase of myopia in their schools as a national calamity; and it is an evil that cannot be too carefully guarded against in every country.

It is not our purpose, however, just now, to discuss this branch of the subject. The causes and remedies for myopia in schools have been frequently dwelt upon in these columns. Still, we would not lose the opportunity here of calling attention to one of the necessities of modern education—that of having the "doctor in the school-room."

Whatever the special measures adopted for the ocular hygiene of schools, the assistance and supervision of competent medical authority is the essential measure that should be at the bottom of all attempts at systematic hygienic reform.

QUACKERY IN THE RELIGIOUS PRESS.

Several of the religious papers have attempted to defend their course regarding the publication of quack advertisements. The burden of their argument appears to be that the editors of these periodicals do not pretend to judge whether or no this or that medicine is what it is represented to be in the advertisement. So long as there is nothing morally wrong in the wording of the quack's card, nothing in it that would jeopardize the spiritual welfare of the readers, it is allowed to take its place among announcements of purely religious wares. From every other form of wickedness, except quackery, the readers of these papers appear to be protected. Every other kind of questionable advertisement is rejected to keep these papers respectable.

The excuse of want of knowledge of the real character of the quack advertisement is an exceedingly lame one for any intelligent editor to make. He cannot absolve himself from the responsibility on such a plea. As a matter of fact, there is not an editor or publisher of a religious paper in the land who does not know that he is doing wrong by giving the quacks a respectable hearing. The quacks understand this, and are willing to pay more for an advertisement in a religious paper than in any other.

From a business point of view, these frauds understand that every announcement that appears in a religious paper bears the stamp of Christianity. The editors of these journals virtually guarantee this. At least, the Christian people over the country are taught to think so. Thus it is that, while these Christian men are supposed to be sowing the good seed, they are being paid by the enemy to allow the sowing of tares also. But, unlike the enemy in the parable who came by night, the quack walks in broad daylight in company with the sower himself, and with his free permission plies his damnable trade.

It is useless for these Christian editors to argue that the public should know of these things and judge for themselves. The public, through them, have a right to know only of such things as are guaranteed to be pure, good, and true. If the editor is not certain that such is the case he is bound to ascertain. The members of the medical profession who are subscribers to these papers will gladly enlighten any of these journalists. At least they can leave no other excuse for the religious editors than that they are paid well for serving the devil in the livery of heaven.

THE MEDICAL AND SURGICAL HISTORY OF THE WAR.

The medical profession has placed itself fairly on record as endorsing the value of "The Medical and Surgical History of the War." This is as it should be. The government has been generous to the profession in placing such a work within reach of a fair proportion of medical scholars. The editions have been reasonably large and have been rather lavishly distributed. Of course, a goodly number of medical gentlemen do not possess the volumes, and are willing to obtain them gratuitously. These are they who are constantly writing to friends in Washington, asking for copies. The failure to supply free copies has somehow or other given the impression that there is a necessity for extra editions. The truth, however, is, that there are plenty of these volumes which are not appreciated by such as originally received them from Congressmen, and which can be obtained at comparatively low figures at the various book-stands over the country. We say this much by way of announcing that a bill has been introduced in Congress which authorizes the public printer to reprint, from the stereotype plates, an edition of 50,000 copies of each of the four volumes heretofore issued from the government printing-office. Should the bill become a law, these books will be for gratuitous distribution by members of Congress.

On behalf of the profession we can inform the public that there is really no necessity for such an appropriation. It is quite evident that the profession is being made a cat's paw in this business. Under the circumstances it cannot, nor will it endorse the measure. The medical man wishes to have his rights, but he does not ask the government to squander money for what it does not need. We are confi-

dent that this measure is not intended for the benefit of the profession. If the bill should by any artful legislative dodging be passed, it is safe to say that the comparatively few numbers will be distributed to the profession. At best the passage of the bill would be a shameful waste of the people's money. We ask our readers to be cautious how they sign any petitions which may be circulated with such a view.

THE ETHICS OF CONSULTATIONS.

Such as are interested in the study of the ethics of consultations will find some new points brought out in a letter in another column. The case is stated with great clearness, the logic of the correspondent is sound from beginning to end, and the consultant is clearly shown to be in the wrong. The latter committed a gross breach of etiquette by his cautionary advice to the attending physician, in the presence of the patient, regarding the defects in the catheter. The excuse for such behavior, which was made by an appeal to natural tendencies, is quite novel, although not entirely satisfactory. Under such circumstances the attending physician is always compelled to act on the defensive, by firmly declining to be placed in a false position to his patient. Our correspondent will have the sympathy of all who have been placed in similar relations.

THE BENIGNITY OF SYPHILIS.

We have devoted considerable space in the present number to the paper by Prof. Dana. The subject of which he treats is one of much interest, and as such will doubtless commend itself to the progressive and thoughtful practitioner. The tables are so arranged as to give at a glance the history of each of the large number of cases, and furnish the data upon which the conclusions are based. It appears quite evident, from the study of these cases, that syphilis often runs a mild course without classical treatment, and despite unhygienic surroundings; that it frequently has a tendency to spontaneous cure, and that its present benignity appears to be due to a gradual change in the poison itself.

Unless we are prepared to admit that seamen as a class have a peculiar immunity from syphilis, the conclusions will have a much wider range than the author originally intended for them.

Dr. Clark McDermott died recently at his residence in Dayton, O. During the war, Dr. McDermott became very prominent, being appointed Medical Director of the Army of the Cumberland, and subsequently being in charge of the Nashville Hospital, the largest in the army. After the war he was made Surgeon-General of Ohio. Dr. McDermott had established a high reputation for his surgical skill, and he was greatly beloved for his social qualities. He lived in New York city for a few years, and is well known by the older surgeons here.

Reviews and Notices of Books.

A Practical Treatise on Tumors of the Mammary Gland; embracing their Histology, Pathology, Diagnosis, and Treatment. By Samuel W. Gross, M.D., Surgeon to and Lecturer on Clinical Surgery in the Jefferson Medical College Hospital, etc. Illustrated by twenty-nine engravings. New York: D. Appleton & Co. 1880. Pp. 246.

Dr. Gross has taken a step in the right direction, and his able monograph on mammary neoplasms will not fail to stimulate the earnest student to further efforts in the path thus marked out. American pathology is still in its infancy; the practical bearings of this science are little understood and less appreciated. Perhaps this is partly the fault of the pathologists; certainly no blame can attach to the science of pathology. Books like the present sow a plentiful seed, and if the mind of the profession but furnish a receptive soil, the planted grains are bound to grow and blossom. Then, indeed, we may look forward to the time when the cultivation of this science will find its proper reward by a just appreciation on the part of the profession of its past endeavors and the high aim of its future objects.

There is enough to criticise in the book before us, but we cannot explicitly set forth when and how Dr. Gross might have improved the quality of his work. The tendency of the volume is so good that the critic for once feels justified in abstaining from pointing out the nether side, with its imperfections, errors, and deficiencies. Work of the kind before us should receive the encouragement of just recognition of its intrinsic value and general meritoriousness, rather than have its prompting ardor checked or even cooled by the proclamation of discovered mistakes or insufficiencies.

The author states that he has sought to harmonize structural with clinical observations, and in this way he appeals directly to the interest and judgment of both pathologist and surgeon. In this way also his pathology loses the flavor of an abstract science, pursuing ends of its own, which are entirely distinct from the objects of practical every-day treatment. This may be considered a concession on the part of high science to mere art, but in our country and at the present day it is a *sine qua non* of a book intended for the use of the practitioner.

Gross' classification of mammary growths corresponds in all essential respects to that of Virchow, as modified by Lücke. Tumors springing from tissues of the connective group, including fibroma, myxoma, lipoma, chondroma, and sarcoma, are distinguished from neoplasms of epithelial origin, viz., adenoma and carcinoma. Angioma and neuroma, which represent complex structures, are again placed in a separate class. With much diligence the author has collected various statistical data illustrative of the life-history both of the tumors themselves and of the patients who carry them. We doubt, however, whether the many tables of percentages invariably possess a high value and justify general inferences, not because statistical evidence is not the safest guide to knowledge, but because often the number of cases observed by Gross was too small to make numerical deductions therefrom permanently valuable. Gross is partial to foreign sources of information as regards the record of other than personal cases. There appears to be no good reason for this

predilection, for American medical literature contains descriptions which are fully as good as those of the average European observer. Early surgical interference is warmly advocated, and we hope not in vain. A timely hint concerning the axillary lymphatic glands is given. They should, according to the author, be first attacked when constituting a hard and knobby tumor, because it appears useless to attempt interference with the primary growths until it is ascertained that they can be removed. On the whole, it may be said that the work of Gross contains much valuable information, partly original, and in part compiled from other works; that the woodcuts are, with some exceptions, very mediocre productions, and that the book has not, as its author would have it do, filled the void of a "systematic and strictly accurate treatise." No book on pathology could come up to such a standard.

Diagnosis and Treatment of Ear Diseases. By Albert H. Buck, M.D., of New York, Aural Surgeon New York Eye and Ear Infirmary; Instructor in Otology, College of Physicians and Surgeons, New York. Wood's Library of Standard Medical Authors. New York: Wm. Wood & Co. 8vo, pp. 411.

This work is a record of individual experience chiefly, as the preface tells us and as a perusal of it shows; but the record is of an experience so rich in material and so well digested that the result is a very complete text-book upon the subject.

It is eminently a practical work, especially adapted to the practitioner who is already familiar with anatomy and pathology, and its title shows the real character of the book, which is treatment of the diseases of the ear. At the same time it is not dogmatic, and the views of others with whom the author differs are recognized briefly, and generous credit is given where the labors of others have been drawn upon.

Beginning with a sketch of the physiology of the ear, the methods of examination are given, and the rest of the book is taken up with diseases of the auricle, of the external auditory canal, of the middle ear (non-purulent forms), of the middle ear (purulent forms), fractures of the temporal bone, diseases of the mastoid process, miscellaneous conditions of the drum-membrane, ossicles and tympanic cavity, and aural disease in which the labyrinth is believed to be involved.

A knowledge of anatomy, physiology, and histology is presupposed, as the short chapter devoted to physiology, although written in a very interesting and concise style and with excellent illustrations, can hardly be regarded as complete. In the chapter upon examination of the ear it seems to us that a little too much stress is laid on certain instruments and not enough upon the principles which determine their use; probably many practitioners would take exception to the remarks upon the various forms of specula and upon the choice which is made by Dr. Buck; but when one knows what one is to look for, but little can be said in favor or against any one of the modern forms.

Whether the methods advised for the removal of cerumen by instruments rather than by syringe will will prove as safe and effectual a means in the hands of the average practitioner, who will necessarily have but little practice in such manipulations, is quite a question; in expert hands it is safe. But the use of caustic potash for such a purpose, as quoted from another author, cannot be too severely condemned, and the quotation had better have been omitted.

The chapters on acute purulent inflammation of the tympanum are excellent, the treatment of the subject being clear, systematic, simple, and thoroughly efficient; they are just what the general practitioner requires for help in this most important and serious disease. Boracic acid would probably have received a more favorable notice if the author had been so fortunate as to have tried Morson's pulverized acid, which is literally an impalpable powder.

In the references to perforations of Shrapnel's membrane, an article in the *Boston Medical and Surgical Journal*, for March 26, 1874, is as worthy of mention as the first upon the subject published on this subject.

On the whole, we can say that we have read the book with both pleasure and profit, and can pronounce it sound, practical, and safe, destitute of irrelevant theories, and without the attempt to be encyclopedic, which renders so many works uninteresting.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Stated Meeting, January 10, 1881.

A. E. M. Purdy, M.D., President, in the Chair.

The special order of the evening was the reading by Dr. Charles L. Dana of his prize essay, which was entitled:

ON THE BENIGNITY OF SYPHILIS; BEING A STUDY OF THE DISEASE, ESPECIALLY AS IT AFFECTS SEAMEN.

When the reading of the paper was concluded, Dr. F. R. Sturgis, being called upon by the Chair, remarked that it was a difficult one to discuss in an intelligent manner, since it dealt to so large an extent with statistics. If he understood the writer properly, the essay had been confined principally to the consideration of secondary syphilis, and he thought that almost every one would concede that the disease was undoubtedly benign in its early stages.

Dr. Dana here interrupted Dr. Sturgis to explain that the latter had misunderstood him on this point, since he had used in his paper the nomenclature employed in the United States Marine Hospital Service, which was that of the English authorities, who excluded the term tertiary, and included in the general term secondary syphilis both the secondary and tertiary manifestations of the disease as generally understood in this country.

Dr. Sturgis then went on to say that the great danger in syphilis was from the late developments of the affection. Although he believed with the writer that in the vast majority of cases the disease was benign, yet there was a certain proportion in which, either directly or indirectly, it proved fatal, and in preparing any statistics of the disease (as he had himself found by experience) it was extremely difficult to sift these cases, to which other causes of death were likely to be assigned. He did not think that syphilis was especially benign in sailors, but rather that in all classes at the present day the proportion of cases in which the late manifestations were of a serious character was comparatively small; while he agreed, with Dr. Dana, that, as a rule, such venereal troubles, as gonorrhœa, chancroid, and in-

flammatory bubo, really caused more disablement than syphilis proper. This result might, perhaps, be due to the better treatment which was now employed.

With regard to the matter of nomenclature, he could not but object, though with all due reverence, to that used by the English authorities, who still used the terms hard and soft chancre, while they excluded the tertiary stage of syphilis altogether, regarding what are understood as the tertiary manifestations as mere sequelæ of the disease. It was a fact that these late symptoms were just as amenable to the effects of mercury as the early ones; and he believed that the opinion was steadily gaining ground that mercury was of the greatest possible service in tertiary syphilis. After a few remarks on heredity in this connection, he said that he thought the true way to get at the complete facts as to the gravity of syphilis was to compare the total mortality with the whole number of cases of syphilis extant.

Dr. George H. Fox said that, apart from the improved methods of treatment now employed, he believed that in New York, at least, syphilis was in the vast majority of cases at the present day a benign disease. Those who had not given much attention to the subject still believed that a large number of the cases met with are characterized by the terrible features which were described so graphically in some of the older books; but experience proved this to be a great mistake. Viewed from a social point, indeed, syphilis was one of the greatest scourges of humanity; but from an individual point of view it was not of so much consequence. He had no doubt that there were a number present who were familiar with the affection as it was now generally met with, who, if allowed the choice, would actually prefer inoculation with syphilis to suffering from chronic rheumatism or malaria. Among his patients at the New York Dispensary he had sometimes met with those who were prejudiced against the use of mercury, and in such instances he had often been surprised to observe what a normal course the disease usually pursued, even when no mercury was resorted to, and how well the patients remained after three, four, or five years. At the same time he was a very strong advocate of the use of mercury in syphilis, and he was in the habit of employing it in almost every instance. He believed, however, that the hygienic condition of the patient was too often neglected, as well as the resort to other remedies which were also of decided service. Thus, he regarded iron as but little inferior in value to mercury itself; and he believed that iodide of potassium should be given more largely than it was, especially in the early stages. In those whose health was otherwise broken down, syphilis occasionally resulted very seriously; but in those who were in good health, regular in their habits, and surrounded by proper hygienic conditions, it almost invariably ran a benign course, and he was glad for one that the benignity of the disease had thus been prominently brought before the profession.

Dr. H. G. Piffard thought that the statistics which had been presented were somewhat puzzling. His impression, in regard to English soldiers and seamen at least, was that they were disabled to a considerable extent by venereal disease, and that in them syphilis was rather less benignant than in civil life. The accounts of the disease as it existed a hundred, or even fifty years ago, were somewhat startling; and although we occasionally saw duplicates of its severer manifestations as then met, they were certainly very rare at the present day. This tendency toward benignancy he believed to be due to the improved methods of treatment which had been adopted, whereas, fifty years ago, he thought the disease was frequently aggravated by the treatment resorted to. Sometimes syphilis now ran its course in two years without treatment, and was purely benign throughout; but the majority of cases would not pursue this benign course if left to themselves. Formerly it was thought necessary always to salivate the patient with mercury; but at the present day salivation was regarded as injurious instead of beneficial. He was of the opinion, however, that too much iodide of potassium was now given, particularly in the early stage of the disease. In common with Dr. Sturgis, he believed in the use of mercury early and late, and in giving as little iodide of potassium as possible. It seemed to him that cases which would have done well on mercury alone frequently did not progress favorably if the iodide was used. The patients were subject to constant relapses, and these relapses were very difficult to control. It was this class of cases that were often met with in our hospitals, suffering from tertiary syphilis.

He regretted that the term tertiary syphilis had been expunged from the nomenclature used in England and adopted by the United States Marine Hospital Service. Mr. Jonathan Hutchinson had called the tertiary manifestations merely sequelæ of the disease; but one thing was certain, viz., that such conditions were never met with unless the patient had first had syphilis. In the marine hospitals we did not know whether the serious lesions occurred or not, since in fatal cases death took place from asthenia, which might be produced in many different ways. In all hospitals, be believed, there was a certain mortality which could be traced to the effects of the syphilis, which it was customary to set down to other causes.

Dr. Thoms said that he was familiar with the disease as it occurred among seamen, and that the conclusions of the writer accorded, in the main, with his own experience. At the same time, it was well to bear in mind that there was a great mortality from other causes among seamen; and it might be possible that a certain proportion of this was due to the remoter effects of syphilis. Thus, in the Seamen's Retreat, on Staten Island, as well as in the United States Marine Hospital here, there was a large mortality from disease of the lungs, and it seemed to him that this was increased by syphilis.

Dr. Morrow had not arrived in time to hear the essay, but he doubted whether the term "benign" could be applied with propriety to a disease like syphilis, which impressed the system so profoundly that outbreaks of it were liable to occur ten, fifteen, or even twenty years after the appearance of the initial lesion, and in regard to which it was still a mooted question whether it could really be cured or not. The statistics of the French hospitals, he thought, demonstrated that it was not a benign affection, and he mentioned particularly those of Fournier, who found that, out of 167 pregnancies, no less than 145 of the offspring were born dead, either prematurely or at full term. The more we learned of syphilis, he said, the more likely were we to consider it a severe disease. Many years ago Fournier had followed Ricord closely in his method of treatment, and had announced about six months as sufficient to maintain it. Twelve or thirteen years later, however, he had laid down a set of rules for the treatment of syphilis, in which it was taught that it was absolutely necessary to use mercury for two or

three years; while still more recently he had expressed the opinion that four years was the minimum period during which the treatment should be kept up.

Investigation had demonstrated, he continued, that a great many diseases which had been formerly regarded as severe were in reality directly attributable to syphilis. It was an affection characterized by marked anæmia, and among its results were amyloid degeneration of the liver, kidneys, and other organs, while it also had a tendency to produce diseases of the lungs, eye, brain, and spinal cord. According to the best and most recent authorities, syphilis was answerable for an immense number of affections of the nervous system.

Dr. Bangs differed somewhat in his opinion from the last speaker, and thought it was altogether appropriate that the term "benign" should be applied to a disease which was evidently so much less severe than it had formerly been, a result which he believed, in common with some of those who had preceded him, was due to a great extent to the improved methods of treatment which had been employed during the last few years.

Dr. Bulkley, on the other hand, was not willing to let a paper in which syphilis was characterized as a benign disease go forth from the society without a protest. It was much more widespread in its effects than many of those who had spoken seemed to realize. In his own public practice one-tenth of all the cases of skin diseases which he met with were of syphilitic origin, and when it was remembered that one-third of the whole number were cases of eczema, it could readily be seen how large a proportion of the remainder were syphilitic. In private practice he had found that one-sixteenth of the cases were syphilitic, and here eczema constituted rather a larger percentage of cases than in the other class of patients. From facts like these he thought it altogether wrong that syphilis should be allowed to go out in the community with the endorsement of a learned body like this as to its being a benign disease.

The later manifestations of the disease were the ones of greatest danger and severity, and especially syphilitic affections of the nervous system, of which there were a great variety. Grave lesions of the eye also were very apt to occur late in the course of syphilis, and he mentioned two cases of this which had come under his own observation. In one of these (where one of the eyes was entirely lost from choroiditis, and the other only saved with difficulty) the trouble appeared nearly twenty years after the original chancre from which the syphilis had developed. He also mentioned the case of a lady who had come to him to be treated for tubercular syphilitic ulceration about the lip, which had been pronounced epithelioma and lupus by other physicians, and which readily yielded to antisyphilitic treatment. The husband of this lady had suffered for a long time from persistent neuralgia, and this also was removed by the same kind of treatment. He certainly thought it was a mistake to apply the word benign to a disease which frequently gave rise to such grave disorders as amyloid degeneration of the liver and kidneys, and he believed, notwithstanding the assertion of one of the previous speakers, that every gentleman present would hesitate very decidedly before he accepted syphilis in his own person in preference to rheumatism or malaria. It was undoubtedly true that many of the severe features of late tubercular syphilis were due either to improper treatment or the unfavorable physical condition of the patient, but at the same time it was unfortunately a fact that we very frequently met with the loss of the nose or with grave disease of the bones in syphilitic subjects. These cases were, indeed, exceptional; but there were a sufficient number of them still to be seen to convince us that the disease giving rise to such conditions was of no light order. The fact also that syphilis caused so many still-births and so many diseased offspring (as had been before remarked) was enough to demonstrate that it was a malignant, and not a benignant affection. Since it was such a serious trouble, therefore, the treatment was of the utmost importance, and mercury, the use of which had formerly been abused to so great an extent, was undoubtedly the most useful agent that we possess for the eradication of syphilis. At the same time, he believed also in giving iodide of potassium, in small doses, and considered iron an adjuvant of the utmost value.

Dr. Sturgis remarked that a protest such as Dr. Bulkley seemed to advocate would reflect seriously upon the committee on prize essays, and he could not but believe that the great majority of the members of the society were in harmony with the general sentiment of the paper as to their opinions upon syphilis. He thought Dr. Bulkley's experience as regards the frequency of the loss of the nose and other serious consequences was very exceptional, as neither his own nor that of many of the largest observers in this city was in accordance with it.

Dr. Fox suggested that syphilis might be both a benignant and a malignant disease. Thus, mumps was regarded by all authorities as belonging to the former class of affections, and yet it was well known that occasionally a malignant case did occur. There was no doubt whatever that syphilis did sometimes occur in a malignant form—and occasionally despite the best treatment; but this did not alter the fact that in the great majority of cases the disease ran a benign course. He wished to enter a protest, also, and that was against looking at syphilis from an exclusively dermatological point of view, as Dr. Bulkley seemed to be inclined to do. The cutaneous manifestations of syphilis constituted only one of the many features of the disorder, and he thought it was the experience of all that syphilitic skin-troubles were among the most amenable to treatment in the whole list of cutaneous affections.

After further remarks by Drs. Petzold and Piffard, the writer of the paper brought the discussion to a close. He explained that he had only aimed in his essay to show that, as a rule, in seamen the disease syphilis ran a course which was mild in character; and of this fact he was, from quite extended observations, very positive.

As to the mortality from the disease, Dr. Dana stated that he believed that not very many deaths occurred from it among sailors. In his experience he had never known a man to die from syphilis in the institution with which he had been connected, which was the largest in the United States Marine Hospital Service. There were also remarkably few affections of the nervous system in connection with syphilis in seamen; and the same was true, so far as his observation went, of Bright's disease, and amyloid degeneration of the liver and other organs. Chronic diseases of lungs he found to be extremely infrequent in those sailors, the Scandinavians, who had syphilis the most. He did not deny that the disease affected seriously the offspring of syphilitic parents; but, at the same time, it was true that such offspring either died when very young, or else got rid of the effects of the dis-

ease as they grew up. He thought, therefore, that Dr. Fox had been right in regarding syphilis in general as a great deal milder than many chronic diseases; and he had seen many cases of it in which it was not much worse, as regards its disabling effects, than an ordinary attack of measles. In conclusion, he advocated a pure mercurial treatment in the early stages, as preferable, in the great majority of instances, to what is generally known as the "mixed treatment."

CANDIDATES FOR MEMBERSHIP, WITH NO LEGAL AUTHORITY TO PRACTISE, EXCEPTING A DIPLOMA FROM A HOMŒOPATHIC OR ECLECTIC COLLEGE.

Before the society adjourned Dr. Ellsworth Eliot presented the following resolution:

Resolved, That our delegates to the State Medical Society be instructed to obtain a decision from the State Society whether candidates who have no legal authority to practise physic and surgery, excepting a diploma from a homœopathic or eclectic college of this State, should be admitted to membership in county medical societies which have the right of representation in the State Society.

After a brief discussion the resolution was referred to the Comitia Minora, to be reported upon at the next meeting of the society.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 12, 1881.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

DR. SATTERTHWAITE presented a specimen, with a written history, for a candidate.

DR. J. W. HOWE exhibited a lipoma weighing three pounds and twelve ounces, removed from the scapular region of a female fifty years of age. The tumor had been growing twenty years. The principal part of the wound united by first intention.

EPITHELIOMA OF PENIS.

Dr. Howe also presented specimens of epithelioma of the penis, removed by operations from patients aged respectively fifty-four and seventy years.

The first specimen was removed from the older patient. The disease was confined to the glans penis. The wound healed promptly, but the patient subsequently died of œdema of the lung.

The second specimen was one of cancer of nearly the entire penis. Amputation of the organ was performed in the usual way, and the wound healed without trouble. It was found, however, after the patient was able to get about, that his urine spattered over the inside of his thighs, and produced extensive excoriations. Dr. Howe, in order to remedy the difficulty, performed a supplementary operation, which consisted in splitting the urethra in the median line under the pubes, and sewing the edges of the mucous membrane to the corresponding edges of the integument. By this procedure the parts were made to imitate the labia minora in the female, and served the purpose of directing the urine in a continuous and solid stream clear of the thighs.

ACUPRESSURE SAFETY-PINS.

Dr. Howe also called attention to a device which he had used to advantage in controlling the oozing from the severed corpora cavernosa. It consisted of two diaper safety-pins, constructed for this purpose, which were applied to either side of the stump in such a manner as to perform acupressure.

DR. B. A. WATSON, of Jersey City, presented a specimen of gunshot wound of the transverse colon, followed by acute general peritonitis. The points of interest in the case were the almost complete absence of shock, the absence of tympanites for the first four or five days, and the comparatively low temperature during the whole course of the disease.

The society then went into Executive Session.

Correspondence.

THE ETHICS OF CONSULTATIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—Believing that the following narration, bearing upon medical ethics, will not be without interest and profit, I venture to ask for a brief space in the columns of the RECORD.

Dr. A., the attending physician in a case somewhat tedious but not serious, was requested by the patient to have Dr. B. meet him in consultation the following day. At the same time he was informed that Dr. B. had already been there, but learning that another physician was in attendance, declined service, except as consultant. Circumstances which are not pertinent to the story caused Dr. A., at first, to hesitate, but he finally consented.

The physicians met. Dr. B., on approaching the bed, saw on the table a Jacques' catheter which had not the "velvet eye," but which was in perfect condition. He examined it, commented on its defects, and suggested how to render it free from danger by rounding off the margins of the eye with a hot glass rod. Then turning to the patient, who had been listening to his cautionary advice, he proceeded with his examination, during which he remarked, disjointedly: "Well, you are not as bad as you might be;" "the seminal vesicle is greatly distended;" "the prostate is not enlarged;" "the doctor and I will put our heads together, and if I can suggest anything that will hasten matters I will do so."

After the examination the two doctors retired to an adjoining room for further consultation. Dr. B. stated that he did not know that he had anything of special value to suggest, that the patient would undoubtedly be well in a few days, but that a certain remedy might hasten the result. He had previously endorsed the diagnosis and treatment of Dr. A. The suggestion was declined by Dr. A. on account of the manner in which Dr. B. had acted in the presence of the patient, and because neither physician believed the remedy to be of essential value, and, furthermore, because such a course would, under the peculiar circumstances of the case, unjustly injure the attending physician. After a free interchange of views, Dr. B. withdrew his suggestion, and said he was willing to let the treatment go on unaltered.

The following day Dr. A. received a note from Dr. B., in which he stated: "I accepted the criticism of my remarks to the patient due to a manner for which I am no more responsible than I am for the shape of my nose or the color of my hair." He then proceeded to criticise the action of Dr. A., and submitted the following propositions: "My argument is this—I submit it in the best spirit, without a shade of ill-feeling: 1, a patient, even when doing well, has a perfect right to demand a consultation; 2, his physician must accept or decline; 3, accepting the meeting the physician is bound to follow any reasonable suggestion offered by the party called in."

To the first and second propositions Dr. A. gave his unqualified assent. To the third he assented, if by "reasonable suggestion" be meant one which, in the judgment of the attending physician, would materially benefit the patient; otherwise he claimed the right to dissent, and pointed out that the code of ethics clearly defined the manner in which differences should be settled. He fully admitted that the attendant was bound to carry out any suggestions offered by the consultant, that were *agreed upon in the consultation*, but that beyond this, duty did not require him to go.

Two points in the above narrative seem to me worthy of serious consideration. I refer to them in no vindictive spirit, but because I believe them to be the munitions behind which many are seeking to defend themselves from the shafts of a foe nearer home than those whom they have injured. I contend for a principle and not against the man. First, it is astonishing that a physician, capable of occupying a position of marked prominence in the profession, should consider himself no more responsible for the manner described in the above not over-tinted picture, than he is "for the shape of his nose or the color of his hair." Further comment is needless. Secondly, it is surprising that he should so far misunderstand the code of ethics as to believe that it would sanction the dogma that an attending physician "is bound to follow any reasonable suggestion offered by the party called in."

Permit me, in conclusion, to offer the following proposition, as a comment upon the above dogma, which, after all, is the salient point at issue:

I hold that in consultations "the responsibility must be *equally* divided between the medical attendants; they must *equally* share the credit of success as well as the blame of failure;" that differences "should always be avoided, if possible, by mutual concessions, as far as they can be justified by a conscientious regard for the dictates of judgment;" that the consulting physician "should observe the most honorable and scrupulous regard for the character and standing of the practitioner in attendance; the practice of the latter, if necessary, should be justified, as far as it can be consistently with a conscientious regard for truth, and no hint or insinuation should be thrown out which could impair the confidence reposed in him or affect his reputation."

PRACTITIONER.

NOTE ON A HOUSE-EPIDEMIC OF "FALSE DIPHTHERIA OR SPREADING QUINSY,"

ORIGINATING IN LOCAL CAUSES, AT AN ISOLATED HOUSE, AND NOT SPREADING BEYOND THE MEMBERS OF THE INFECTED FAMILY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In September, 1879, I was called to see a sick family residing in a small house on a range of hills back of and above the junction of the Snake and Clear Water Rivers of Northern Idaho.

In an old abandoned claim shanty, built of rough lumber, raised but a few inches from the ground, ten feet by twelve in dimensions, lighted by a window but sufficiently large to meet the requirements of the U. S. Land Office, I found a family consisting of three (3) adults and four (4) children, sick with what was supposed to be diphtheria. A few moments before my arrival a boy ten years old had died. A second boy, seven years old, was in articulo mortis, and died a short time later. The father, who had been the first attacked, was convalescent, the other members of the family were in various stages of the disease.

A careful examination of these cases determined that there was an acute inflammation of the tonsils, accompanied by great swelling and induction. That in each case the pharynx was more or less involved. That there was a considerable accumulation of a tenacious mucus upon the inflamed surfaces, *but no diphtheritic membrane*. In each case the febrile symptoms were pronounced, the pulse was full and hard, the skin was dull and entirely free from any eruption.

The entire family gave evidence of being broken down by long exposure to unhealthy conditions. Their persons, clothing, and surroundings were filthy. The surface of the ground about the house was covered by débris of all kinds, including human excrement and the droppings of animals. The house was so small that much of the household effects stood in the open air. At night the two adult males slept in a wagon-box, leaving the house to the use of the mother and children. A scanty supply of water was obtained from a shallow pit a few feet from the house.

The locality was one of almost absolute isolation. The nearest house was six miles distant, the surrounding country being an open cattle range, through which no public road passed. The house was reached by a long drive over the rough prairie, which has an elevation of at least 800 feet above the bed of the Snake River. The soil of this prairie is thin, over-lying a gravel bed. It is covered with short bunch-grass. On it there is no decomposing vegetation or standing water. The season was hot and dry; there had been no rain for many weeks.

The family were at once removed to a larger house, some miles distant, where they could command an abundant supply of pure water, and a thorough system of domestic policing was instituted. An immediate improvement took place, and all made satisfactory recoveries, save a boy four years old, who, while apparently progressing to convalescence, died suddenly.

In but one case did any sequela of the disease occur; in the person of a girl, twelve years old, a submaxillary abscess formed and was discharged. In no case were there any symptoms of paralysis.

This seems to have been an outbreak of a "filth disease," which had its origin in the insanitary conditions in which the family had lived. They had occupied this house for upward of a year. The women and children had not been away from home for months. The men had worked as harvest hands, and the father was taken sick while from home; but there had been no sickness upon any of the farms on which he had worked, and the disease did not spread in his family until a week after his return home. There had been no diphtheria on the country side, and no cases of similar disease occurred in other families, although the sick and dead of this infected family were cared for by several good men and women, themselves the heads of large families.

These cases seem to be corroborative of the statements made by Dr. C. B. Fox in the *British Medical Journal* for December 7, 1878.

ELY MCCLELLAN,
Major and Surgeon U. S. Army.

December, 1880.

New Instruments.

IMPROVED HYPODERMIC SYRINGE.

By SAMUEL WHITALL, M.D.,
NEW YORK.

The accompanying cut represents a hypodermic syringe I have been using for about a year; and the hope that it may prove of equal value to others, who, like myself, have had frequent occasion to be annoyed by the piston syringe refusing to work when most urgently needed, has prompted me to call attention to it.

The idea was suggested to me by having seen the description of Dr. Holden's syringe published in the RECORD some years ago. His plan was to attach the needle directly to a rubber bulb of a given capacity. Such a syringe is open, however, to many objections, the most serious of which are, that one cannot tell when the fluid is all injected, and the rubber bulb will enlarge with use. At first I modified the doctor's syringe by attaching a bulb to the barrel of an ordinary syringe, but, although it worked very well, it was awkward to manage.

The construction is so simple as to require little explanation. A piece of rubber tied over the expanded end of the barrel supplies the place of the piston.

To charge the syringe, depress the rubber with the index finger, and insert the needle, previously attached, into the solution to be injected, and then remove the finger. Atmospheric pressure at once fills the syringe to the required point.

To inject, proceed as with an ordinary syringe, depressing the rubber slowly with the index finger till the injection is completed.

It is better to take up just the quantity of solution required for the injection, which can readily be accomplished by removing the syringe from the liquid the moment it is charged to the desired point. Air at once enters the syringe and the fluid gravitates to the needle end.

One rubber will last for months, and the instrument is always in working order. Should the rubber give out it is but the work of a moment to tie a new one on.

It works better with a somewhat coarser needle than those commonly used.

Sometimes a bubble or two of air may enter the connective tissue, but the emphysema is harmless.

Two points must be remembered: to keep the needle end of the syringe downward while injecting, and not to remove the index finger from the depressed rubber till the needle is withdrawn from under the skin.

The syringes are made by J. Reynders & Co.

COLOR-BLINDNESS.—A bill to appoint an international commission, to agree upon standard tests for color-blindness and visual power in navies and merchant marines, has been introduced into Congress.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 23, 1881, to January 29, 1881.

GREENLEAF, C. R., Major and Surgeon. His leave of absence, granted him in S. O. 158, series 1880, from A. G. O., extended to May 1, 1881. S. O. 20, A. G. O., January 26, 1881.

WILLIAMS, J. W., Major and Surgeon. Par. 9, S. O. 2, C. S., A. G. O., relating to him is revoked. S. O. 20, C. S., A. G. O.

BENTLEY, E., Major and Surgeon. Announced as Acting Medical Director of the Department until the arrival of a medical officer his senior. G. O. 2, Department of Arkansas, January 17, 1881.

TAYLOR, B. D., Captain and Asst. Surgeon. The operation of Par. 4, S. O. 14, C. S., A. G. O., so far as it relates to him, suspended until March 1, 1881. S. O. 20, C. S., A. G. O.

GARDINER, J. DE B. W., Capt. and Asst. Surgeon. Relieved from duty at Camp Herachuca, and assigned to duty at Fort Mojave, A. T. S. O. 7, Department of Arizona, January 15, 1881.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 29, 1881.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

Jan. 29, 1881.	0	6	170	12	41	121	26	0

THE DAILY AMOUNT OF URINE, according to Dr. E. S. Wood, ought to be carefully ascertained in order to make sure a diagnosis of Bright's disease. A knowledge of this, and also of the daily amount of urea, is often of as much service as an examination of the urine for albumen and casts. These latter Dr. Wood has found in the urine of patients with acute rheumatism, who have been taking salicylic acid.—*Boston Medical and Surgical Journal.*

IN CHRONIC ARSENICAL POISONING the liver is the organ apt to contain the most of the drug, while the brain and nerves contain the least, if the preparation used is the oxide.

POISONOUS PIGMENTS.—From a study, by Dr. P. Grondhomme, of the effects of the various materials used in preparing aniline dyes (*Chicago Medical Review*), the following conclusions have been reached: Benzol is poisonous, its vapor producing dizziness, tinnitus, nausea, and drowsiness. Naphthalin is harmless. Anthracin has only a somewhat irritating effect on the mucous membranes. Nitro-benzol produces dyspnœa, dizziness, drowsiness, tonic and clonic convulsions, ending often in general paralysis and death. These symptoms may not appear until twenty-four hours after the poison has been taken.

Forty-four cases of acute poisoning by nitro-benzol have been reported, fourteen being fatal. Aniline is undoubtedly poisonous. Of the dyes that are prepared from it, rosaniline, magenta (contrary to general belief), and alizarin are known to be harmless. At the factory of Meister & Co., in Germany, where over a thousand operators are employed, not more than three per cent. of the sickness is caused by the coal-tar products. It is quite probable, on the whole, that the clothes dyed in aniline colors are, as a rule, not at all dangerous.

The Last Illness of "George Eliot."—The *Lancet* gives an account of the last illness of George Eliot. She was feeling quite well up to five days before her death. On December 20th she was taken ill, however, and Mr. G. W. Mackenzie being called in, found her suffering from a laryngitis and fever. The next day the laryngitis was better, but she still had fever, and complained of pain in the right iliac and lumbar regions. In the evening, though these symptoms abated, she was not so well. Her breathing was frequent, and she was restless and uneasy. On the next day, December 22d, she was still worse, there being a dyspnœa and general prostration. No local complication could be discovered, however. In the evening, Dr. Andrew Clark visited the patient in consultation. She was then still worse. She lay on her back, with the shoulders raised. The eyes were closed; the face was of an ashen gray color, the lips livid, the breathing hurried, and the pulse small, irregular, and frequent; a loud pericardial friction-sound was heard over the heart. Attempts were made to give brandy and food, but without avail, and the patient rapidly failed. Although George Eliot died thus suddenly, she had not been well for eight years. In 1873 Dr. Clark diagnosed a renal calculus. In 1874 she had several attacks of renal colic, with hæmaturia; in 1876 she had an attack of cystitis. From that time she had suffered, at intervals, with renal colic and hæmaturia. In 1880 the urine had steadily decreased in density, and had, at times, contained pus or albumen. In October last she had a slight attack of calculous pyelitis. During the last few years she had visibly failed in health and strength.

¶ Typhoid Fever Carried by Milk.—Another instance of the probable carrying of the typhoid fever infection by milk has been brought to light at Portsmouth, England. The history of the cases show that the milk that carried the disease was from a dairy in which there had been a case of typhoid fever. The person who attended the typhoid fever case milked the cows, and the stools of the patient were carried through the room where the milk stood.

Vivisection—A House Divided against Itself.—At the late meeting of the Scottish Society for the Prevention of Cruelty to Animals, held in Edinburgh, a suggestion was made that the society direct its attention to the question of vivisection This project was strongly opposed by Councillor Sloan, who declared that the saving of a single life was of more importance than the lives of all the cats and dogs put together. (Loud hissing and cries of "Shame.") He heard ladies hissing, but he repeated that a human life was not to be compared with that of all the cats and dogs that are nursed and pampered in the New Town of Edinburgh. (Cries of "Shame," and the Rev. Mr. Fisher—"Life is God's gift to animals as well as to you.") He did not wish to sanction cruelty, but were the discoveries of Dr. Keith and others to be balked by mere sentiment? He was sorry to see people who, before they would give up wheezy, pampered brutes for scientific purposes, would rather give up their domestics. (Hissing and great interruption). In spite of these remarks the society agreed to act against vivisection.

Medical Legislators.—There are thirteen doctors in the Tennessee Legislature.—*Nashville Med. Jour.*

Homœopathic Achievements.—A homœopath, of the name of O. B. Bird, is collecting an epitome of homœopathic achievements. The first "achievement" which we see recorded is this: "Diphtheria, 1856, Dr. P——, Washington, 100 cases, 3 deaths. Under allopathic treatment two-thirds of all cases died. Franklin County, N. Y., Dr. H——, 1860–62, treated 1,000 cases of diphtheria, lost 8 per cent.; best allopath lost 25 per cent. Lowell, Mass., severe epidemic dysentery: allopaths lost 10 per cent., Drs. H—— and S——, homœopaths, lost 1½ per cent.," etc. And yet homœopathy is losing ground.

Medicine a Trade.—The *Lancet* is exercised over the fact that in the London Post-office Directory, medical men are put down under the head of "Commercial." Lawyers have a separate section.

A Natural Bone-Setter.—Madame Dal Cin, the Italian bone-setter, of whose history and methods we gave an account about a year ago, has returned to her native country. She was a skilful *masseur* and a discreet employer of marsh-mallow poultices. She made a great impression upon some of our Brooklyn neighbors.

Skin-Grafting.—Dr. James E. Pilcher, in the *Annals of the Anatomical Club*, describes the latest methods of skin-grafting antiseptically. Warts are preferable if they can be obtained. Grafting wherever there is loss of integument secures the following results:

1. A more perfect cure in all cases.
2. A cure where in many cases there would otherwise be a permanent and annoying ulcer.
3. A cicatrix more soft and mobile, and less liable to destructive ulceration than in the ordinary process.
4. Entire absence of contraction or deformity.

To Abolish Vivisection.—Mr. Henry Bergh has begun his campaign against vivisection again by introducing a bill at Albany for its prevention. It is the same bill that was defeated a year ago.

St. Louis Medical Colleges.—According to the *Missouri Republican* there are in St. Louis seven medical colleges, four irregular and three regular. Each of these has a right under the law to admit its students to the clinical advantages of the city hospitals. The City Health Commissioner has written a letter saying that this privilege has become a huge nuisance to the hospital officers as well as to the patients. Some legal measures to check the abuse are said to be necessary.

Attending Medical Societies.—There is, after all, but a small proportion of the profession that attends with any regularity the meetings of the societies. And there is a very good reason for this. Although occasionally there are excellent papers and discussions, this is not the rule, and whether the paper is good or not, there is a large amount of talk that is simply inane following it. Societies are haunted by a few persons for whom age or accident secure respectful hearing, and who insist on using their privileges of the floor, whether they have anything to say

or not. Now it is not profitable to listen to discussions upon the value of whale-oil in pleurisies, for instance. Nor can one be aroused to enthusiasm by a two-hour oration on the habits of the tape-worm. Society meetings illustrate the curious physiological fact that when any accident, prenatal or otherwise, arrests the development of the cerebral mass, the posterior part of the third left frontal convolution generally remains intact, or may even be the seat of an extra molecular activity. There are a certain number of persons, generally, but not always in the decline of life, who will get up and talk, whatever may be the subject, and one could easily experience the idea of eternity by listening to them, we will say for a day. . . . . On the whole, a person is hardly to be blamed for staying away from most society meetings, since he runs an excellent chance of being bored, and since what is best in the proceedings can be found later in the medical journals. This is, of course, only one way to look at the matter. From a higher standpoint it might be considered a duty to go and do some work to make the meeting better. Furthermore, there is no doubt that if a New York medical society sets out to have a good meeting, as occasionally happens, there can be nothing more instructive.—*New York cor. of Chicago Medical Journal.*

Learning Obstetrics at Vienna.—In a letter to the *Philadelphia Medical Times* concerning the Medical School at Vienna, Dr. Robert W. Johnson says: "Few courses humiliate a beginner more than obstetric operations on the cadaver, and few are so satisfactory. The books, so glib about the application of forceps, the simplicity of turning, dwell rightly on the horror of craniotomy; but mere black and white does not impress one with the difficulties in the same way as an endeavor before a watchful instructor to deliver the dead woman, *per vias naturales*, of one of the numerous still-born children that are utilized. The man who takes two courses, at least, on this important topic, from different assistants, will glean a variety of opinions as well as experience that he will never forget. One thing, however, it is to be hoped, he will never obtain, and that is the alacrity with which students and instructors leave the dead-house for the lying-in room to make examinations with hands imbrued with the blood of the dead, and, it may be, consciences dyed with the blood of the living. I cannot but think that the awful inroads of puerperal fever, and the numerous deaths thereby, arise largely from this criminality in attempting to satisfy the meagre sentiment that foreigners generally have for women by a paltry wash of carbolized water after post-mortems on even puerperal subjects. It requires more than a basinful of the 'multitudinous seas, incarnadine,' with permanganate of potash, to rub out the 'damned spot' so acquired, and, God knows, Americans had better stay at home than learn abroad to carry, under the badge of their healing office, desolation to the hearth of a confiding family. Much as I respect these Viennese teachers for their attainments, and the good they have done in advancing obstetrical science, I cannot help looking on them as guilty of something near homicide while they permit or advance such criminality." Dr. Johnson speaks in much the same way of the vulgarity and brutality of the instructors in venereal diseases.

Mr. Tennyson on Doctors and Nurses.—Mr. Tennyson's new volume of poems contains one poem which, says the *Medical Press and Circular*, might have been written in the interests of the treasurer of Guy's Hospital, its chief end and aim being the glorification of the nurse and the abasement of the medical practitioner. The poem, entitled "In the Children's Hospital—Eminie," is supposed to be spoken by a nurse who is nothing loath to exhibit her own exquisite sensibility, which stands out all the more brightly against the dark, rough background of medical callousness and cruelty which she coincidently depicts.

The spirit of this anti-medical lyric is revealed in the first verse:

Our doctor has called in another; I never had seen him before,
But he sent a chill to my heart when I saw him come in at the door,
Fresh from the surgery—Schools of France and of other lands,
Harsh red hair, big voice, big chest, big merciless hands!
Wonderful cures he had done; oh, yes! but they said too of him
He was happier using his knife than in trying to save the limb,
And that I can well believe, for he looked so coarse and so red,
I could think he was one of those who could break their jests on the dead,
And mangle the living dog that had loved him and fawned at his knee—
Drenched with the hellish Dorali—that ever such things should be!

"To say," continues the journal referred to, "that the description which we have quoted is the very opposite of the truth is to fall far short of condemning it in deserved terms. It is not only outrageously false, but, taken in connection with the rest of the poem, it is obviously a malicious libel on a profession that has in some way incurred Mr. Tennyson's displeasure, which he vents in no measured language. Again and again a bitter animus against medical men comes to the surface."

We have read the poem criticised so fiercely by our English contemporary. Except in the verse quoted, however, we did not find any especial evidence of malignant feeling against the medical profession. At any rate, the profession will not be likely to suffer very much in reputation or prosperity from the utterances of Mr. Tennyson. Mr. T. is a great poet, but chiefly a ladies' poet, and he has a wonderful power of melodious expression, but it generally serves the cause of a moaning sentimentality (*vide op. cit.*). Besides, Mr. Tennyson has been losing some sixty grains of brain-tissue for a number of years. And *he* doesn't know it.

Statistics of Medical Education in the United States.—The Report of the U. S. Commissioner of Education, for the year 1878, contains some interesting statistics regarding the medical, dental, and pharmaceutical schools of the country.

The number of these schools reported to the Bureau during the year was 106. These had 1,337 instructors and 11,830 students. The regular school of medicine and surgery reported 64 institutions (the number now is 69); 915 instructors; 8,279 students; 2,506 graduates; 46,065 volumes in libraries; $1,685,250 in grounds, buildings, and apparatus; $214,347 in productive funds, yielding an income of $13,186; and tuition receipts to the amount of $289,398. The eclectics reported 6 institutions; 51 instructors; 448 students; 211 graduates; 3,000 volumes in libraries; $161,000 in grounds, buildings, and apparatus, and $8,960 receipts from tuition. The homœopathists reported 11 schools; 158 instructors; 1,215 students; 363 graduates; 39,800 volumes in libraries; $349,000 in grounds, buildings, and apparatus, and $95,471 receipts from tuition fees.

The dental schools report as follows: number, 12; instructors, 161; students, 701; graduates, 218; volumes in libraries, 505; value of grounds, buildings, and apparatus, $68,000; receipts from tuition fees, $60,734.

The pharmaceutical schools number 13; instruc-

tors, 52; students, 1,187; graduates, 380; volumes in libraries, 5,175; value of grounds, buildings, and apparatus, $155,000; receipts from tuition fees, $25,487.

The medical degrees conferred in course were 3,814; honorary degrees, 4. There were, during the same year, conferred in course 222 degrees in theology; 1,000 in law; 6,367 in arts.

The total amount of educational benefactions during the year is $3,103,289, of which schools of medicine received $8,762. Of this sum, however, regular medical schools received only $4,662, one of these schools being the New York Medical College for Women.

The increase in medical students over the previous year (1877) was 615, the total number being 11,830. The increase of the previous year was 1,082.

Treatment of Otorrhœa.—The following plan is employed by Dr. H. Gradle (*Chicago Medical Review*). The applications should be made by the physician himself. If there is any fetor in the discharges, the ear is cleansed and a five per cent. solution of carbolic acid, warmed, injected. The meatus is then plugged with vorated cotton. Next day the fetor has generally disappeared, and the discharge is thinner and less copious. The well disinfected ear is then dried with absorbent cotton and powdered boracic acid is poured in through the speculum while the head is inclined on the other side, until the meatus is half filled. The ear is then plugged with clean cotton. The powder absorbs all discharge and keeps it from decomposing. The application may not have to be renewed for three or even eight days. A lessening and finally a stoppage of the discharge occur rapidly in most cases. In some cases where the boracic acid did not act promptly iodoform was an efficient substitute.

Dangers of Chlorate of Potassium.—Attention has been called to the danger from the excessive use of this drug, by Dr. A. Jacobi and other physicians in this country. The subject lately received prominent attention from the Society of Physicians, at Vienna. In a debate before that body, Dr. Th. Billroth related a case of sudden death following the administration of gr. cl. of the drug, in two doses. The drug was being used for vesical catarrh. Billroth stated that not more than from ʒ ss. to ʒ j. should be given per day.

Ollier's Method of Treating Bronchocele.—A correspondent of the *Lancet*, writing concerning the hospitals at Lyons, France, gives an account of M. Ollier's method of treating bronchocele. This is described as novel and efficacious. The surgeon dissects off carefully all the coverings of the tumor, and then applies to the surface an oval piece of Canquoins paste a quarter of an inch thick and just the size of the exposed tumor; after the paste has been on for four hours it is removed, and the tumor dries up and shrivels away without constitutional disturbance or pain, the cure being effected in from three to four months.

The Determination of the Sexes.—Of the various theories that have been offered to explain the determination of sexes, the most plausible is that which assumes that the sex is determined by the relative maturity and vigor of the parent. When these qualities reside in the male, the offspring will probably be male, and *vice versa*. This view has some support from the fact that the proportion of birth (including still-birth) of males is to that of females as 143 to 100. Furthermore, the statistics of Hofacker and of Saddler corroborate the theory. According to the former, the proportion of male births to 100 females is as follows: father younger than mother, 90.6; father and mother of equal age, 90; father older by 1 to 6 years, 103.4; father older by 6 to 9 years, 124.7; father older by 9 to 18 years, 143.7; father older by 18 or more years, 200.

Saddler's statistics show very similar proportions. The actual proportion of living males to females at birth is, however, only about 105 to 100. The great losses of still-births, therefore, are among males, and are due chiefly to the larger size of the male child. The living male infant is about one-third of an inch longer and one-third of a pound heavier than the female. The average difference between the male and female fœtus is still greater. A large expenditure of valuable life, therefore, is produced by the pelvic strait being too small. Dr. Charles Roberts, who gives (*Lancet*) the above statistics, urges the necessity of a better physical education for girls, and intimates that the present practice of encouraging the intellectual development of women develops their crania at the expense of the pelvis, and leads to deplorable results. These results will be probably, in time, sterility, or, more probably, a lessened proportion of males. According to this philosophy, therefore, the enlargement of the pelvis should be one of the great goals of educational effort.

This is but a narrow view of the matter, however. There are many other factors in the question, and statistics so far show an excess of males in the most highly civilized races as well as in those where women is only a slave or a drudge.

The Expansiveness of Obstetrics.—A correspondent of the *British Medical Journal* calls attention to the fact that in the programme of the Obstetric Section of the coming International Medical Congress there are only two subjects that come strictly under the head of obstetrics. The remaining subjects are those of hysterotomy, laparotomy, Battey's operation, etc., all which belong really to the domain of surgery. There is, perhaps, no objection to obstetrics expanding, but things should be called by the right name, and laparotomy is not midwifery.

The Secrets of the Consulting-Room. — The Philadelphia *Medical Times* earnestly urges its readers in Pennsylvania to use their influence in securing the passage of a law recognizing the confidential relations between physician and patient, and protecting the former on the witness stand. It is proposed to copy the law that exists in New York. This law, enacted in 1828, has worked very well.

The Cost of Charity in France.—The Board of Charity (Assistance Publique) received last year, from various sources, the sum of 15,633,000 francs (about $3,000,000). Its expenses for the same time were 28,865,000 francs, leaving a deficit of 13,232,000 francs.

Dr. Brown-Séquard is lecturing at the Collége de France, Paris, on the "Dynamic and other Changes arising in the Animal Organism from Distant Irritation."

Paralysis from Thoracentesis.—M. Dumont Pallier reports to the Société de Biologie a case of empyema treated by thoracentesis, in which irritation of the pleura by injection of fluid gave rise to successive crises of contraction of the right side and

paralysis of the left side. These phenomena, which rapidly passed off, were followed by sweating and excessive lachrymal secretion. They were attributed to reflex action successively upon the left and the right cerebral hemispheres. M. Lépine had previously reported hemiplegia, lasting for fifteen days, excited by a like irritation of the pleura.

French Gingerbread does not reach this country in great amount. Those who do get it should know that it is made of flour, glucose, carbonate of potash, chromate of lead and chloride of tin. This is the statement made by Drs. Moynier and Galippe.

Success of the Edinburgh Provident Dispensary.—This institution has just finished its first year as a provident dispensary, and congratulates itself upon its success as such. It was formerly a free dispensary. The number of successful provident dispensaries in Great Britain seems to be constantly increasing.

Bloodless Excision of the Mammary Glands.—Several cases are reported by Dr. Leisrink, in the *Centralblatt für Chirurgie*, in which he removed the mamma without the loss of a drop of blood. The patient had pendulous breasts, hence favorable for the operator. He prepared an apparatus having two metal rods at the sides and a movable cross-piece at each end. These cross-pieces could be screwed closely together. The breasts were first emptied of blood by pressure and manipulation, and then the apparatus adjusted. He found it much superior to any modification of the Esmarch bandage.

Tonga.—The much-vaunted cure for neuralgia is not to be the product of any particular plant, but rather a kind of herbalist's composition powder, for which the formula was prepared by a German resident of the Fiji Islands.

Infant Mortality.—Still-births, illegitimate births, and crime generally, have been steadily increasing in France during the past thirty years. But France is the most civilized of all nations!

Scientific Affection.—A French chemist is said to have condensed the body of his deceased wife into the space of an ordinary seal, and had her highly polished and set in a ring. He made a nice income by betting with lapidaries and others that they could not tell the material of the seal in three guesses, and, after pocketing the money, would burst into tears and say, "It is my dear, dear wife."

Incomes of Medical Men.—Physicians and surgeons in England have occasionally left large means, notably Sir Henry Halford and Sir Astley Cooper. The latter received the largest fee on record in England—$5,000 thrown to him in a night-cap from the window by a patient after lithotomy. Sir Charles Locock, the Queen's accoucheur, returned income tax one year on £30,000, which is believed to be the largest income ever received by an English medical man. Sir William Gull and Sir James Paget very likely make to-day from £10,000 to £15,000 a year; the very large sums paid for journeys out of town largely swell their incomes. Sir William is said to have received $2,000 for a visit to Ireland. Probably the excessive exaggeration about lawyers' and doctors' incomes is largely due to the fact that it becomes noised abroad that a man in a certain year made £10,000, and it is assumed forthwith that this is his normal income. Few lawyers and doctors in New York have died really rich.

Dr. Topinard succeeds the late M. Paul Broca as editor of the *Revue d'Anthropologie.*

Low Temperature in Disease.—Dr. L. Woods, of Pittsford, Vt., writes: "Having seen but few low temperatures recorded, and wishing to know the lowest temperature with which a person can live, I report the following case, hoping it will call out others.

"December 6, 1880.—In a case of uterine cancer, I found a temperature of 91½°, pulse 88, at 9.45 P.M., nine hours before death took place from exhaustion. Owing to circumstances beyond my control, I was unable to obtain another record nearer death. At 9 A.M. of same day temperature was 94⅘°.

"December 13th.—In a case of pneumonia, on the seventh day, the temperature had fallen to 97¼°; pulse, 56. On the eighth day, 95⅘°; pulse, 52. On the ninth day, 97½°; pulse, 48; and the tenth day, 97⅘°; pulse, 54. The highest temperature was 103½°, on the second day; highest pulse, 120. This case recovered.

"In neither case was there any hemorrhage or diarrhœa to account for the low temperature. In both cases it was carefully taken in the axilla.

"I find a case of typhoid fever recorded by Dr. Parkes, in which 'on the seventeenth day of the fever the temperature was as low as 93°; blood was largely passed in fluid stools the night preceding.' I do not learn whether the patient recovered or not. Dr. Cheyne records a case of typhus fever in which 'a few days before death he observed the temperature to fall to 95°.' In yellow fever, a fatal case is reported with a temperature of 96°. In cholera, Dr. Finlayson, of Ceylon, found the temperature in the axilla from 92° to 97°, while Dr. Keir, of Moscow, found it under the tongue to be from 79° to 88°.

"I notice several other cases reported, but, as the temperatures were taken under the tongue, do not consider them reliable, and consequently of no value."

Philadelphia Doctors.—One of the characteristics of professional life in Philadelphia, writes the correspondent of the *Chicago Medical Journal*, is its comparative freedom from those bitter feuds and heart-burning jealousies which prevail in other large cities, where there is more inequality of success, and where the race for wealth is more reckless and furious. The profession is liberally supplied with social and professional organizations of all kinds. An attempt at social enjoyment on a large scale has been initiated this season in the form of a series of receptions given by the County Medical Society, the largest and most representative society of the city. These receptions have been a marked success, contributing to the popularity and membership of the society.

Dr. Robert Barnes has resigned his appointment as obstetric physician to St. George's Hospital. Dr. Barnes is engaged with his son, Dr. Fancourt Barnes, in preparing a manual of midwifery for the press.

Original Lectures.

INFLAMMATION OF THE UVEAL TRACT.

A Clinical Lecture.

By D. B. ST. JOHN ROOSA, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

(Reported for The Medical Record.)

Gentlemen—This man, thirty-eight years of age, comes to us on account of symptoms affecting his left eye. He is a laboring man, and has been employed in a gas-house. He complains of pain over the left side of the forehead, along the left side of the nose, and in the remnants of the first upper molar tooth. This tooth, he says, has been inflamed about six times, but it has caused him no inconvenience during the last two years until the present attack of disease in the eye, which manifested itself ten days ago. At that time he first suffered from toothache, which has persisted, and in addition he now has pain over the left side of the forehead, along the left side of the nose, and in the left eye. There is no pain on the opposite side of the face or in the opposite eye.

Four years ago he had trouble with his right eye, which subsided under treatment. Of that I will speak hereafter, for he was then also under my care. The present attack, so far as symptoms referable to the eye are concerned, began with a feeling as if something had gotten into it; and besides this, in going about at his work, he hit his head against a gas-pipe. Then he began at once to have pain in the eye and head, especially in the occipital region.

Let us now look at this man's left eye. The conjunctival and the subconjunctival vessels are overfilled. The radiating vessels of the ciliary region are distended. The iris is moderately dilated, not fully. Atropine has been used. The color of the iris is nearly unchanged; perhaps it is slightly darker than the iris in the fellow eye. The cornea is perfectly clear. The eyeball is tender to the touch, especially just under the situation of the superior rectus muscle, at a point a little behind the ciliary portion of the eye. There is some photophobia, and there is slight lachrymation.

There is then in this eye hyperæmia, congestion of the conjunctival, the subconjunctival, the scleral, and the ciliary blood-vessels, and there is tenderness of the eyeball—a tenderness referred to the choroid coat. Let us next see whether or not there is impairment of vision.

We will first test the right eye, and we find that when the left eye is covered he can read No. 20 of Snellen's test-types at twenty feet; that is, his vision in that eye is normal, or $\frac{20}{20}$. When the right eye is covered we find that he reads with the left, or the affected eye, No. 100 of the same test-types at twenty feet; that is, his vision in that eye is $\frac{20}{100}$, or much less than normal. So far as he knows, he could see as well with his left as with his right eye before the present attack of inflammation. His vision then has probably been reduced in the affected eye from $\frac{20}{20}$ to $\frac{20}{100}$. The salient features of his symptoms, then, are these: he has great pain referred to the eyeball and directly in the course of the branches of the fifth pair; he has tenderness of the eyeball, hyperæmia, and congestion perhaps of the various parts mentioned, and he has marked impairment of vision. He has been under treatment at the Manhattan Eye and Ear Hospital eight days.

Now, let us inquire as to what was done for his eye during the two days prior to his attendance at the hospital. He says that he washed his eye, first, with camomile tea, and afterward with *breast-milk*. We shall never be free from the superstitions of the dark ages until we cease to attribute mysterious virtues to compounds or mixtures which are efficacious, if efficacious at all, by reason of some ordinary property that can be secured in some simple way. The use of milk from the breast of a woman as a collyrium is as absurd to the scientific mind as the cure of the sick by the incantations of a painted Indian; and yet white people still attribute mysterious virtues to certain substances, as we have just heard. This man, who had a sad experience four years ago, when he had serious trouble in his right eye, which required a long time to effect a cure, profited but little by that experience, and for two days persisted in making these applications, none of which reached the seat of the disease. Unfortunately, he made a diagnosis for himself: he thought that he had gotten something into the eye and produced a conjunctivitis, that he had injured the nerves of the head by a blow from a gas-pipe, and that he needed nothing except warm fomentations. From the very beginning he had serious, deeply seated disease of the eye, about which I am to lecture to you this afternoon.

A word about the tooth. I find the stump of a tooth not at all sensitive, but covered with tartar, as are the other teeth, and it may have something to do with the disease of the eye from which he is now suffering. I am unable, however, to find in its present condition the exciting cause of his affection of the eye.

What shall we name the disease whose symptoms we have already enumerated? One gentleman says that the intense pain in the part of the eyeball indicated means choroiditis. Not especially, however. Intense pain in the eyeball occurs in glaucoma, in neuritis, in iritis, in cyclitis, in keratitis, in choroiditis, in certain forms of conjunctivitis; but the tenderness in the part of the eye in which this man experiences it, does indicate choroiditis, although the pain does not specially do so. Now, what other symptoms of those pointed out made you think of choroiditis? We have: first, pain; second, loss of vision; third, ciliary injection; fourth, tenderness of eyeball; and fifth, sluggish, moderately dilated pupil. The tenderness, I have said, indicates choroiditis. Yet we may and do meet with choroiditis with no tenderness of the eyeball. But what is the primary affection from which this man probably suffers? One gentleman says cyclitis. I am always surprised that students in medicine, in diagnosticating diseases of the eye, think first of the rather uncommon, or at least less frequent diseases. There is cyclitis here, but we name affections of the eye from the part which *predominantly* suffers. Of course he has conjunctivitis. He could hardly have the trouble already admitted to exist without having more or less inflammation of the conjunctiva. It is possible that the disease from which he now predominantly suffers had its starting-point in the vessels of the conjunctiva; but the conjunctivitis has been lost sight of practically in the course of this disease, which is much more serious than a conjunctivitis.

This man certainly has *iritis*. The irregularity and change in color in the iris show this. I believe that he also has choroiditis and cyclitis; in other words, he has *inflammation of the uveal tract*, and that forms the basis of my lecture. A case of inflammation of the uveal tract. Why uveal? Why tract? Uveal on account of the color and quantity of the pigment, and tract because of its extent, for the uveal tract is made up of the iris, the ciliary body, and the choroid.

In the diagram on the blackboard, we see the iris with its epithelium, its muscles radiating and circular, its posterior surface covered by a layer of pigment-cells, its blood-vessels supplied largely from the ciliary arteries, its nerves from the fifth pair—probably also from the sympathetic—and from the third pair and its lymph-vessels.

Here we also see the ciliary body, consisting of the ciliary muscle and ciliary processes, with its large supply of blood from the same source which supplies the iris, its nerves, its layers of muscular fibres, and its pigment-cells; and then back of that we see the choroid, the vascular tunic of the eye, the part upon which it depends for nutrition, abundantly supplied with pigment, also having muscular tissue in its structure which so predominantly exists in the ciliary body and is largely found in the iris. The uveal tract comprises these three portions of the eye: the choroid, the ciliary body, and the iris.

Now, I believe that, instead of saying iritis so much as we do, it would be better to say inflammation of the uveal tract; for it is seldom that iritis stops at the limits of the iris, it is very seldom that cyclitis is limited to the ciliary body, and choroiditis, though more commonly limited, does not infrequently extend beyond the choroid, yet less rarely than does iritis or cyclitis extend beyond the boundaries of the iris and the ciliary body. All of these diseases may extend the one into the other. The tissue is substantially one, from the iris back into the choroid. In this case we can dismiss the cornea and the conjunctiva from our consideration, and talk chiefly of iritis. Inflammation of the choroid exists, as I believe, because there is such marked tenderness upon pressure made on the eyeball at a point a little back of the ciliary region. I know that he has iritis from the character of the congestion, from the sluggishness and turbidity of the pupil, and from the character of the pain, and we can hardly believe that serious inflammation can exist in these two parts, with a sound condition of the connecting band, the ciliary body.

VARIETIES OF IRITIS.

In many of the books iritis is divided into a number of varieties. Sufficient for your purpose, however, is the following classification: first, there is hyperæmia of the iris which you should understand and study carefully. When a patient has a discolored iris which moves sluggishly under atropine, and not at all, under the influence of light admitted, as you have so often seen done here, by shutting the eyelid over the eye, and then quickly pushing the lid back with the ball of the thumb—when there is ciliary congestion, but when there are no adhesions, when there is no swelling or exudation into the anterior chamber, we may content ourselves with the name hyperæmia of the iris. I have no doubt that this man's loss of vision is due to the clouding of the anterior chamber, and that is the particular symptom which distinguishes *serous iritis* from hyperæmia, and distinguishes it from the next form, which is the most important—namely, *plastic iritis*, in which the exudation is sometimes so marked that you can see it in the pupillary space, and so great that the iris becomes glued to the capsule of the crystalline lens.

There is another form of iritis met with, chiefly after injuries of the iris such as come from accidental wounds or from cataract operations, viz.: *suppurative* iritis, the most dangerous of all, and that which usually destroys the eye.

There are, then, four forms of disease of the iris: 1, hyperæmia of the iris; 2, serous iritis; 3, plastic iritis; and 4, suppurative iritis. There is another classification, that dependent upon the cause, which is quite important. But all forms of the disease require the same local treatment, and present many symptoms in common. We have iritis from syphilis, from rheumatism, and from other causes. Iritis from syphilis is the most frequent form of the affection. Wecker gives it at 70 per cent. of all cases, but I should be inclined to put the figures higher rather than lower.

Then we have iritis from rheumatism, and iritis from other causes, such as injuries, and it is possible that there may be an iritis produced by decaying teeth. Excessive weeping may sometimes, I think, be a cause of inflammation of this part of the eye. Certainly there may be keratitis from the same cause, and why not iritis?

Having noted the general symptoms and etiology of the disease, let us, before speaking of the treatment, see if, from the history of the case, we can find the cause of this man's present attack of iritis. I said that I would speak of the affection that he had in the fellow-eye four years ago. That affection was plastic iritis, and I remember very well with what difficulty we dilated the pupil by the energetic use of atropine. By energetic I mean instillations of a solution of four grains of the sulphate of atropia to the ounce of water, from four to eight times a day. By the use of this strong solution we finally succeeded in securing good dilatation of the pupil, and he now has a useful eye, with a round, movable pupil, and iris with good color. The latter fact shows that its tissue was not much injured.

We will now carry the investigation a little farther. As you see, he has a bad tooth, and we will put that factor in, at the same time remembering that he got well of his previous iritis, although, as he says, the tooth at that time was in a bad condition. He denies ever having had venereal disease. I am especially anxious to reach the cause in this case, because the patient has not been made much better as yet by the treatment to which he has been subjected. This man has never had any of the symptoms of syphilis, either primary or secondary, and therefore I see no evidence that his attack of iritis was or is syphilitic. From what does it arise? There is no history of rheumatism. Has it arisen from this diseased tooth, which has involved some of the branches of the fifth pair, and through them developed iritis? At all events, I shall recommend that he have the root of the diseased tooth removed. But I am rather inclined to think the iritis depends upon some cause unknown, and that the decayed, not specially sensitive, but painful tooth, is only one of the factors contributing to his discomfort and preventing him from getting well. One step toward curing the eye perhaps consists in getting rid of the painful tooth; but I am strengthened in the belief that it is not the tooth that has given rise to his eye-trouble by two facts: in the first place, it was in a bad condition and troublesome when the iritis occurred

upon the opposite side, and from which he made a good, though tedious recovery; and in the second place, he improved most rapidly when under the use of mercurial ointment, iodide of potassium, and atropine. However it may be, we will have the remains of the tooth removed, and will hereafter report the result.

TREATMENT.

What are we to do for iritis, whether it be serous, or plastic, or suppurative in character? *The* great remedy, and the one first to be used, is the *sulphate of atropia*. The sulphate of atropia acts directly upon the iris, dilates the pupil, and prevents the plastic exudation from resting on the capsule of the lens and producing union between the capsule and the iris, the most dangerous of all the consequences of iritis.

You must not make any mistakes. The gentleman who answered conjunctivitis in this case must look very carefully that he does not answer conjunctivitis when a patient meets him with hyperæmia of the iris, or plastic iritis in the consulting-room, and that he does not prescribe sulphate of zinc instead of sulphate of atropia. This man is now having instillations into his eye of a two-grain solution of sulphate of atropia, and the strength of the solution will at once be increased to four grains to the ounce of water.

In this case there is severe pain, and hot water is running out of the eye; what shall be done to give him relief? Morphine and leeching are the great agents with which to relieve the pain of iritis, and the leeching is the first in rank of importance. This man will have his bad tooth removed, and then two leeches applied to the temple upon the same side of the affected eye. Besides that, he will receive morphia at night, unless he gets relief from pain by the adoption of the other measures.

As a hygienic measure, cover the eye with a green, or blue, or brown patch to protect it from the bright light, and the patient must not use the fellow eye in close application, because the use of the well eye will increase the irritation in the affected one.

There is another remedy which I would use in all cases where it can be had, and that is warm bathing. The best of all is the Turkish bath, and in obstinate cases of iritis and keratitis it is a powerful adjuvant in the treatment. In New York the Turkish bath can be obtained quite cheaply, and yet, if it be impossible for tl is man to afford it, the ordinary warm bath may be used, having some one to help rub the body well after it.

Then, as regards the internal or the external administration of mercury and the iodides, I am very much inclined not to believe in their use in cases of serous iritis and in cases which are not largely plastic, as I think this case is. Mercury is a remedy commonly used; but I think that where there is no syphilitic diathesis you do very well not to use either mercury or the iodides; I am very much in doubt as to whether they are essential in any except specific cases. When I am in doubt I use mercury and potash.

I have not yet said anything with regard to the pathognomonic symptom in a case of syphilitic iritis. A gummy tumor of the iris is about as sure evidence of the presence of syphilis as we can wish. But there is no general appearance of the iris or the exudation by which you can distinguish the syphilitic from the traumatic, or either from the other forms of iritis.

Wecker says that in the rheumatic variety there is great engorgement of the subconjunctival tissue. I am not quite sure that my own experience has been turned in that direction. I am very apt to rely upon the history of the case to assist me in deciding whether it belongs to this or to that class.

Dr. Chisholm has lately written a paper in which he recommends the salicylate of sodium as a very useful remedy in the treatment of iritis. I do not doubt but that Dr. Chisholm's cases did well while the remedy was being used. The principle upon which it was used is the same as governs its use in rheumatism, and it is believed by that gentleman to have some special efficacy in the treatment of the rheumatic form of the affection. I have had no experience in its use in this class of cases.

Remember, gentlemen, that without reference to the form of iritis with which you have to deal, the first thing to be done when you meet with a case is to use the sulphate of atropia. You must make a correct diagnosis at the beginning. The diagnosis made by the gentlemen, of choroiditis and of cyclitis, would perhaps not have led them into danger, for they would have used, probably, leeches, atropia, morphia, mercury, and the iodides; but the diagnosis of conjunctivitis would have been fatal to the eye.

We will carry out these principles in the treatment of this case, and report the result at some future clinic.

[At the close of the lecture the remains of the tooth were removed, and the gum freely cut, so as to effect a moderate amount of local depletion. The patient made a tedious recovery, after the performance of a paracentesis of the cornea, as well as the other remedies discussed in the lecture. The cause of the attack was never positively determined.]

Improved Dover's Powder.—Dr. S. Mitchell, Jr., of Hornellsville, N.Y., writes: "I have been using for some time lately, Dover's powder, made in somewhat different manner than it is commonly made, and think it a great improvement; and inasmuch as I have never seen anything of the same in medical literature, I think the idea will be as novel to the other members of the profession as it was to myself, when first suggested to me by my brother Dr. J. D. Mitchell. The preparation is simple, and is made by substituting finely pulverized bromide of potassium for the time-honored sulphate of potassa. The bromide must be ground to a powder, nearly as fine as flour, and will be found to answer all the requirements of the sulphate of potassa, as to hardness of particles in promoting 'that minute division and consequent thorough intermixture of the opium and ipecacuanha upon which the peculiar virtues of the compound depend.' This is not all, for the bromide is not only a good mechanical, but a good medicinal agent in this connection as well. It increases the hypnotic virtues of the compound and does not diminish, but rather increases its anodyne properties. The sleep produced by it is refreshing, and delirium very uncommon, my patients often remarking that the powder did not make them 'flighty' as Dover's powder had commonly done. The powder is just as agreeable (?) to take as the old original prescription of Dr. Dover, and its diaphoretic tendency is in no way altered. It works like a charm in many forms of headache."

The More Extended Use of Wire-Cloth for splints, shoulder-caps, buckles, and other surgical purposes, is urged by Dr. J. S. Wight.

Original Communications.

RHINOPLASTIC OPERATION.

By R. W. ERWIN, M.D.,

BAY CITY, MICH.]

PATIENT, Elizabeth H——, German, aged forty-six years; has resided in this country twenty-six years; married, and has had six children, all living except one. Is healthy, and at time of operation was in the menopause. Fourteen years ago she alleges that she ran against an open door, severely injuring her nose; that inflammation followed, resulting, finally, in the loss of the entire organ, including septum. She called it "erysipelas," but whether syphilis or lupus I am not prepared to say. The opportunities for a specific origin were not lacking. The nares were open, and in a front view the deformity was very striking and repulsive, so much so that the public shunned her, and, to hide it, she constantly wore a veil. One of the peculiar results of the restoration of the nose was the recovery of smell. This sense had been absent for years.

After some preparatory treatment, the operation was undertaken May 12, 1879, assisted by Drs. Vaughn and Williams, of this city. The size and shape of the flap had been previously outlined upon the forehead, provision being made for shrinkage. In the greatest diameters it measured two and three-fourths by three inches. A column three-fourths of an inch wide, for joining the septum, was formed at the upper part, mostly from the hairy scalp. The angles for the base were acute (see illustration, Fig. 1).

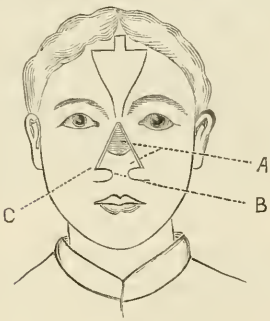

FIG. 1.]

The recommendation of Prof. Packard to hold the knife inclined in making the lateral incisions, forming the flap so as to bevel the edges, was adopted. As soon as dissected up, it was wrapped in oiled linen, and the wound in the forehead closed by sutures, so far as possible, and supported by plaster. The nares were then filled with lint, covered with cosmoline, and the edges prepared to receive the transplantation. An incision was carried down the wrinkle or depression seen on one side of the remnant of nose * to the very base. It was repeated on the other side, and the two corners pulled down for alæ in the new nose. This made a ⌊ space on each side and furnished a firm stay to the coming structure (see Fig. 1). These spaces corresponded to the sharp angles on the base of flap. Grooves were cut on both sides to receive its bevelled edges. A portion of skin as large or a little larger than the thumb-nail (Fig. 1, A), embracing all taken up in freshening the edges, was reflected over the nares. It was left attached along the margin, and being turned over afforded a bed for the bridge, but what was of greater importance, gave a skin, in part, to the under surface, and thus diminished somewhat the subsequent shrinkage in cicatrization. The flap was then brought down, and one side secured at a time by the silk suture, in such a way as to draw the bevelled edges into the grooves upon tightening the thread. The columnar portion passed between the corners for alæ and was made fast. By using the groove the surface for attachment is much increased and the new structure

FIG. 2.

rendered more firm. One suture was tied over a little roll of court-plaster, much to my regret afterward, since it became slack and dirty. A roller was placed on each side of the nose to preserve its shape, and held in position by court-plaster. Water dressing constituted the after-treatment, in addition to the means employed to secure good form. Union by first intention took place throughout. Owing to lowness of the forehead it was decided to take the septum from the upper lip—a decision followed with much trouble. This operation was performed June 18th, and through failure to carry out instructions by keeping parts wet, so much swelling ensued as to push the whole septum outside, where it remained through inability to return it, till healed. The hair-follicles in the extremity of nose prevented prompt union between it and the septum. The mucous surface would secrete a slime that hardened like a scab over it, increasing the difficulty. This condition of the nose was allowed to remain till the 23d of the following January, when I succeeded in carrying it to its proper place by the following method (see Fig. 3): The septum was separated at the nasal end, and divided from top to bottom by a transverse incision forming two columns, *a* and *b*. Two incisions about one-fourth of an inch in depth were then carried from the extremities of the last incision parallel into the nares. The part embraced between them, *c*, was dissected up, leaving the upper end attached. *a*, *c* was then raised and pushed inside the nares

* See Fig. 2, photograph.

where *a* was secured to the under surface of the nose which had been freshened. *c* forming the septum, *b* was then laid down in the gape made by removal of *c*, and secured by suture. Union quickly followed, and thus prevented the possibility of its again drawing out. May 5th—almost a year afterward—I di-

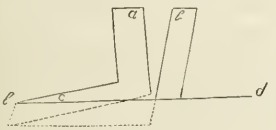

Fig. 3.

vided the pedicle and sunk it into a groove made for it. The photograph marked Fig. 4, gives a front view in the June following—thirteen months after the first operation. The photographs are untouched pictures. At this time the nose was high and possessed very good shape. It will be observed that the scar in the forehead is quite small, and that the change in appearance, expression, etc., is very marked. This is partly due to the removal of wrinkles by cicatrization, but chiefly to moral effect. The points of most interest derived from the case are:

First.—The entire structure should come from the forehead without regard to hair.

Second.—It should be large enough, especially in the vertical diameter, to admit of leaving the pedicle

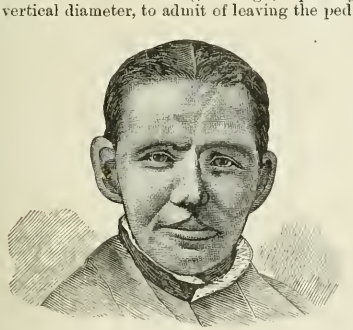

Fig. 4.

for several months undivided. The column for the septum must be long, else it will continue to draw down the tip. The leaving the pedicle attached does more than anything else to prevent the organ from becoming flat. While left it will be necessary to use a little pressure over it to prevent retraction. Court-plaster will do, and may be applied by the patient himself. Should the patient be unwilling to exercise this care it would be better to divide the pedicle as customary.

Third.—Long after the healing a compress on each side of the nose should be worn part of the time (nights will do) to insure symmetry and permanency of shape.

Fourth.—No skin should be wasted in preparing the parts for the reception of the flap, no matter how small. It should be dissected up, and turned over to form a partial cover for the exposed raw surface beneath the bridge.

December, 1880.

NOTES ON A CASE OF HYSTERICAL ARTHRITIC HYPERÆSTHESIA.

By EDWARD T. REICHERT, M.D.,

LATE DEMONSTRATOR OF EXPERIMENTAL THERAPEUTICS AND INSTRUCTOR IN EXPERIMENTAL PHYSIOLOGY, IN POST-GRADUATE COURSE, UNIVERSITY OF PENNSYLVANIA.

Sydenham, many years ago, in speaking of the multiformity of the shapes which hysteria puts on, says that there are but few maladies not imitated by it, and that whatever part of the body it attacks it assumes the appearance of the disease to which the part is liable; and I must say that a more striking illustration of this truth can scarcely be given than in the instance of the present case, in which acute arthritic rheumatism was so closely simulated, as to make it impossible for either my colleague or myself at first to distinguish the case for this disease, and in being led into unavoidable error by thus confounding the two affections.

The following is a brief survey of my notes in the case: Lizzie M——, aged seven years, has suffered since early childhood with frequent and almost constant headaches. She has had no sickness other than the familiar troubles met with in children—such as scarlet fever, chicken-pox, and pseudo-membranous laryngitis—except frequent attacks of rheumatism in the joints, especially so in those of the left leg, and two years ago an attack characterized by considerable pain in the left thigh-joint, with inability to stand on the leg, shooting pains running down the inside of the thigh to the knee, and an accompanying symptomatic fever. The limb, on examination by the attending physician, was found to be shortened an inch and a half, and the case was diagnosed hip disease, and treated as such; and after several weeks of blistering and other similar antiphlogistic methods, the patient got out of bed and was able to limp about with a crooked limb, which finally became straightened, and so far as the physician and parents were able to judge was fully cured (even the shortening). She has a nervous temperament, is easily excited or frightened, and a general history of an emotional nature. The family history, generally, is good, there being no specific or hereditary diseases, save a decidedly well-marked history of rheumatism, and a general prevalence of nervousness throughout many past generations, but no account of anything like what might be construed as attacks of hysteria, except in the mother of the child who had an attack of hemiplegia about four years ago, and from which she fully recovered, without its leaving any traces whatsoever. Every member of both sides of the family, back as far as the memory of the grandmother goes, has had one or more attacks of rheumatism, and some of them had attacks which were so frequent and bad as to seriously interfere, after their recovery from the acute seizures, with the pursuance of their daily work.

On Saturday night (January 8th) the little girl, who had been limping about all day, retired early, because of suffering from considerable pain in the left hip-joint and knee, and having distressing shooting pains running down the inside of the thigh and knee. She was feverish and restless all night, and would frequently cry out with pain. On the next morning a call was left at the office, and on account of my absence from the city, my colleague (Dr. T. N. Bradfield) saw the case. There was a decidedly hyperæsthetic condition of both the thigh and knee-

joints; the thigh was partially flexed and adducted, the joints sore to the touch, and if the leg was moved even the slightest, the pain caused was so intense that the patient would scream, so that any unnecessary manipulation was forbidden. The joints did not appear to be much swollen, much increased in temperature, or colored; and neuralgic pains on the inside of the thigh running to the knee were frequent. There were headache, injection of the sclera, the respirations were increased and heaving, the pulse nearly 130, the temperature 101° F., the skin hot and parched; the urine was small in quantity, seldom passed, and high colored, and the bowels decidedly constipated. Acute articular rheumatism was diagnosed, and the patient at once put on a febrifuge and anodyne mixture with alkalis; and purgative powders were given in addition to move the bowels.

On my return to the city the following morning, I called to see the patient, and found her in a suffering condition, with fever unabated, condition of the urine and bowels unchanged, pains in the joints unmitigated, and indeed, even in addition to the pain in the knee- and hip-joint, it had extended to the ankle since early morning. Fully expecting to find the child improved, I was not a little surprised at her condition. However, as the family history savored so remarkably strong of the rheumatic diathesis, and as her symptoms were so well marked, and my confidence in the recognized diagnostic skill of my colleague such, that did I not for a moment suspect the correctness of his conclusion, but thought that the cause of the unrelief was, in all probability, simply due to the inability of his moderate doses to produce the impression desired. So the doses were increased, and in addition, two and a half grains of sodium salicylate with morphine were given every two hours; and powder of podophyllin with rhubarb and aromatics were given in large doses to move the bowels.

The following morning found the patient but little changed for the better, the fever being but slightly diminished, and a good movement from the bowels obtained. During the night the patient was very restless with insomnia, and had frequent spells of crying, at which times she would complain of her painful joints, and at other times would sing, as if delirious, or at other times talk incoherently. The skin was still hot and parched, the pulse 124°, the temperature plus 100° F., and the urine still in the same febrile condition. The pain in the joints of the left leg was somewhat diminished, but the flexor and adductor muscles of the thigh seemed rigid, and kept the leg firmly but partially flexed and adducted. The extensor muscles of the foot seemed paralyzed. The patient was wholly unable to make the slightest extension of the foot, and it hung down apparently lifeless, although readily movable by my own manipulations. The corresponding joints of the right leg now became affected, and from the little sufferer I gained the information that, as much as the pain was diminishing in the left joints, it was increasing proportionately in those on the opposite side. Distress in the præcordia was also complained of, and cardiac complication was feared; but auscultation and percussion revealed no cardiac trouble. She also complained of such great pain and general distress in her stomach after taking the salicylate, even though given greatly diluted with water, that it was felt necessary to abandon its use. Feeling satisfied that my colleague's mixture was not doing the work anticipated for it, the following was prescribed:

℞. Tinct. verat. virid..... ℥ xij.
Spts. æth. nitrosi..... .... ʒ j.
Morphiæ sulph..... gr. ss.
Potassii citratis..... gr. lxxij.
Syr. zingiberis,
Syr. simplex.....āā ʒ j.

M. Sig.—A teaspoonful every hour until perspiration or decided drowsiness occurred.

After giving half a dozen doses the skin became slightly moist, and the patient felt slightly better. With the addition of two one-twelfth grain morphia powders, she passed a more quiet night, but was sufficiently wakeful to be always ready for her dose of medicine on the very minute of the hour, and at no time was she sleeping but for a few moments at a time. The following morning (Wednesday) did not find her condition essentially changed from what it was on the previous evening, notwithstanding the often repeated doses she had had for the past eighteen hours. The pain was still considerable, the pulse still ranging about 120; the temperature, plus 100° F.; condition of the urine unchanged, and no movement of the bowels since Monday night. Purgative powders were again given, and the mixture continued throughout the day, with additional doses of morphine. By the evening not the slightest drowsiness had been induced, nor had the skin become any more than slightly moistened. The pain in the joints of the right leg grew slightly worse, notwithstanding the morphia, and the left was somewhat improved, although that stiffened, immovable condition remained unaltered. Noticing the nurse rubbing the child's limbs, I inquired if it relieved the pain, and was informed that it did, and on very gently rubbing the child's limb myself—so gently that I scarcely more than touched her—found that before I thrice had done it she screamed out with pain, and upon inquiring the cause of it was told that I "rubbed *up*;" that if I "rubbed *down*" it gave her such great relief, but if "rubbed up" it gave her "awful pain." A few moments afterward she told me that "that horrid medicine gave her such awful pain in her left knee and ankle every time she took it." Not seeing the philosophy of the "rubbing up" acting the very opposite of the "rubbing down," and the relation between the pain in the knee and ankle and the medicine, I, for the first time, suspected the case to be one of hysteria, although I had previously suspected that there was evidently a hysterical complication. So, after endeavoring in very many ways, and for a considerable length of time, to divert the patient's attention from herself, and to get her mind deeply occupied in something altogether foreign to her troubles, I at last succeeded, and at that time took advantage of the opportunity to manipulate her left leg, both in "rubbing up" and in moving it, and to my intense satisfaction found that this operation, which a short while ago apparently gave her such intense suffering, was now performed without cognizance on her part. While continuing to do this, I abruptly recalled her attention to her painful joints, and scarcely had I uttered the words before she cried loudly and said that I was hurting her so much, and implored me to please stop.

Further inquiries informed me that the singing spells which she had on several previous evenings would often occur almost immediately after the child would be complaining of pain, and would be crying from it; and even sometimes in the midst of her crying she would stop suddenly and commence singing, "Oh, my dear little foot!" or refer to her knee,

or to her mother, etc.; at other times it seemed as if the crying and singing coexisted. Yet, when asked if the pain in the joints was constant or intermittent, invariably stated that it was of the former nature, and was not subject to any marked exacerbations. Upon asking the parents if the child had ever suffered with the *globus hystericus*, I was told that she often complained of a choking sensation in the throat, and particularly so after she had been crying from some slight cause.

The case now appeared to me to be a clear one of hysterical arthritic hyperæsthesia, the general family history and the paralytic seizure of the mother, with her subsequent entire recovery, confirming my diagnosis. Consequently, the child was put on twenty minims of fluid extract valerian, every three hours, and, as remarkable as it may seem, after the second dose had had time to operate the fever rapidly subsided, the skin became natural, the kidneys active, and the pain in the joints considerably diminished. The following morning (Thursday) found the child a different being. She had passed a good, quiet night, slept well, and was refreshed; not a trace of the fever was present, the urine became natural in color and quantity, with no pain in the joints, although considerable stiffness remained, and the patient was able to move the left foot a little, which, as will be remembered, hung a few hours previously as if lifeless. Passive movements of the joints were made and the muscles manipulated. The patient was put on general tonic treatment in connection with the valerian, and told that on the morrow she must sit up a little, and be sitting up when I called; but she assured me that she was certain she could not do it. However, without going into the details of the moral treatment with which we are all so familiar, I found her sitting up when I arrived, and in five minutes more, after a determined effort, had her out of bed and, with my support, was walking about the floor, although she stoutly protested a few minutes before that she could not possibly straighten her limbs, or use her left foot.

This case is an exceedingly interesting one, as being an illustration of that very rare class of the multitudinous forms of hysteria in which a well-marked pseudo-febrile condition is attended by decided symptoms and signs of serious organic or arthritic lesion. Hysteria in a child so young is indeed interesting of itself, and but few cases have been reported. Willis, Hoffman, and others of the older authorities, give us but few instances; and even Briquet, with all his extended experience, has only seen eighty-seven cases occurring before the twelfth year; and of 351 cases analyzed by Landouzy, not one was below ten years of age. Hysterical affections of the joints have been referred to by Brodie,* Skey,† Barlow,‡ Meyer,§ and others. Meyer states that one of the leading phenomena which distingnishes hysterical from other affections of the joints is, that in the former the pain ceases in the night; but in the present case it was unmistakably present. Yet, with the other characteristics which he points out, the phenomena of this case are in harmony; such as the transient swellings of the joints, changeability of the temperature of the part, the fact of pressing the joints being no more painful than gentle handling, and the rapid disappearance of the trouble following usual or known methods of curing or alleviating hysterical affections in general. Rosenthal,* the only one of half a dozen authors on nervous diseases with whose works the writer is familiar, refers to this pseudo-febrile condition in speaking of hysterical vaso-motor disturbances, and he says that in several cases he noticed that the temperature did not rise in the axilla above 37.4°—37.6° C. [99.3°—99.7° F.], despite a pulse of 100 to 120; yet, in the present case, the temperature was decidedly in excess of this. The marked tolerance of morphia and purgatives, and the inefficiency of the usual febrifuges to reduce the fever, were no doubt due to the hysteria, and were but symptoms of its existence; while the immediate and marked improvement following the use of the so-called anti-hysterics is equally as suggestive.

A CASE OF
UTERINE DISPLACEMENT.

By M. F. PRICE, M.D.,

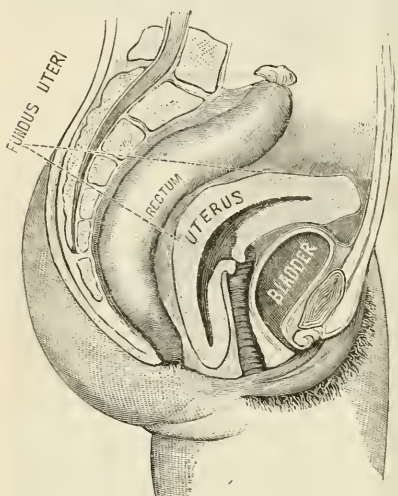
ACTING ASSISTANT SURGEON, U.S.A., FORT STOCKTON, TEXAS.

About December 4, 1879, a Mexican came to me and said his wife was sick, and he wanted some medicine for her. My interpreter was not a good one, and about all the information I could get was conveyed in the term "agua caliente" (hot water), and motions made toward the genital organs. I finally learned that the urine was hot and there was frequent desire to void it. As gonorrhœa is quite common among the Mexicans here, both married and single, I took it for granted this was such a case, and prescribed accordingly.

December 6th.—The man returned and said his wife was no better. I now had a more efficient interpreter, and, after some conversation about the case, I came to the conclusion my diagnosis was wrong, and that I had better see the woman. I therefore rode out to the ranch, and in one of the adobe huts found my patient lying on the ground, apparently in great distress. She was a medium-sized, well-built Mexican woman, about twenty-two years of age. I asked her where her pain was, and she took my hand and passed it over her abdomen to the groins and around to her sides, saying, "Aqui!" "Aqui!" (here, here). I made examination externally and found a tumor (seemingly) above the pubis, which felt like the uterus, but flattened posteriorly. Passing a finger into the vagina, I found what appeared to be a tumor between the recto-vaginal walls, which extended down to and rested on the perineum. The bladder was apparently full, but felt peculiarly puffy. For a long time I could not reach the os uteri, and had about concluded I had a pelvic hæmatocele to deal with. After persistent effort for some time I finally found the os, which was turned forward toward the symphysis pubis and pressed firmly against the bladder, so that it felt like a slit lying crosswise. The cervix uteri was likewise flattened and shortened. The apparent tumor back of the vagina, and the one above the os pubis, I found to be connected; in fact, were one and the same. This condition of things was somewhat puzzling for a time, to say the least. My diagnosis was, finally, that the uterus was much enlarged from some cause, and that the fundus had been by some violence pushed down toward the os, thereby flattening the uterus from above, causing it

* Diseases of the Nervous System.

to assume the shape and position shown in the drawing, and pressing the walls—anterior and posterior—to the positions in which I found them, one to the perinæum and the other above the pubes. Acting upon this diagnosis, I passed the right hand into the vagina from before, and, after drawing it down as far as possible, placed the ends of my fingers against the dependent uterine wall and carried it up, at the same time gently making counter-pressure with the left hand on the anterior portion above the pubes. Persisting in this manœuvre until the posterior wall was carried well up to the promontory of the sacrum, while I was still using considerable force, it suddenly left my fingers and went in its proper place with an



audible "*swoosh*"—the anterior wall simultaneously passing from under my left hand. On further examination I then found the uterus normal in shape and position, but large enough for about three and a half or four months' pregnancy. I now turned my attention to the enlarged and puffy bladder; passed the catheter and drew off about two ounces of pure blood, when the instrument became clogged with clots. I administered an anodyne, enjoined quiet in the recumbent position, and returned to the post.

December 7th.—Found my patient quite comfortable. Drew from the bladder—which was much reduced in size and in a more natural condition—about three ounces of blood. After a thorough examination to-day, I decided that the woman was certainly pregnant, advanced about four months.

December 8th.—Urine passing freely without blood. Uterus normal, bladder nearly so. The woman said she was "muy bueno" (very well). I did not see her again until March 27, 1880. At this time she was very well, and appeared to be advanced to at least seven months' pregnancy. I have not seen her since, but have learned that she was delivered, May 10, 1880, of a large, healthy boy. I refrain from making any comments on the peculiarities of this case, and simply give a description of the condition and the results.

EXTIRPATION OF CANCER OF THE RECTUM.

By CHARLES B. KELSEY, M.D.,

SURGEON TO THE INFIRMARY FOR DISEASES OF THE RECTUM, NEW YORK, ETC.

In a certain number of cases cancer of the rectum has been removed, and has not returned for so long a time as to justify the statement that the patient has been radically cured. In many more cases, though the disease has ultimately returned, a greater length of life and freedom from suffering have been obtained by the entire ablation of the growth than could have been hoped for by any other method of treatment. The operation is, therefore, both a curative and palliative measure, and should be studied from both these standpoints.

The first case of extirpation of the rectum of which we have any record was by Faget, in 1739, and was not for cancer, but simply a removal of the lower portion of the bowel, which had been completely surrounded and denuded by an abscess beginning in one ischio-rectal fossa, and subsequently extending into the other. From that time until 1826 the operation, as a means of treatment of cancer, will occasionally be found mentioned in surgical literature; generally, however, only in condemnation. In 1826 Lisfranc performed the first successful operation for cancer; and three years later his student, Pinault, in a *thèse* reported nine cases, and gave to the procedure a permanent place in literature and practice. In 1833 Lisfranc himself embodied the same ideas in a paper read before the Acad. Royale de Médecine,* and from that time the operation became widely known. Since then it has had its advocates and opponents, and has been subject to many modifications in its performance. For a long time it was coolly received by British surgeons, but within the past decade it has received a new stimulus from the Germans, and at the time of writing it seems about to be fairly tried by the surgical world and judged on its merits.

Almost every surgeon whose name is prominently associated with the operation has had his own favorite way of performing it; and we shall, therefore, speak in detail only of those which have proved most acceptable, and first of those described by Volkmann in his *Klinische Vorträge* for March 13, 1880. He describes three different operations, depending on the location of the disease. The first is for the removal of a circumscribed spot only. This is accomplished by dilating the anus, dragging down the disease, and excising it in such a way that the wound shall not cause subsequent strictnre. When the growth involves the anus the edges of the wound are carefully brought together, stitched with catgut, and a drainage-tube inserted between them. When the growth is entirely within the sphincter, the edges are brought together with equal care, but the tube is inserted through a track made for it, which communicates with the wound above and perforates the healthy skin at a point outside of the border of the sphincter. When dilatation does not suffice, the anus is freely divided down to the coccyx, and this wound is subsequently carefully closed under the antiseptic precautions. In the second class of cases, where the growth involves the whole circumference of the bowel, but not the anus, the latter is divided forward into the perineum and backward to the tip of the coccyx when necessary to give room for

*Mém. de l'Acad. Roy. de Méd., 1833. III., p. 296.

manipulation. The latter of these two incisions is carried as far into the bowel as the lower border of the disease, which is then removed. The mucous membrane above is stitched to that below, the preliminary incisions carefully closed, and a drainage-tube left in the posterior one. In the third class, where the disease involves all, or nearly all of the anus, and of the circumference of the rectum, the entire tube is separated and removed in a cylinder. The same preliminary incisions may be made as in the second class, and the anus is surrounded by a circular cut, which runs outside the sphincter. From this as a starting-point the dissection is carried parallel with the bowel till the upper portion of the disease is passed. By the use of knife, scissors, and fingers the bowel is completely freed, then drawn down to the anus and cut off above the disease, the healthy upper end being stitched to the margin of the skin. In case the peritoneum is opened, the wound is at once stuffed with carbolized sponge, and afterward carefully closed with catgut. The coccyx and part, or nearly all of the sacrum, are removed when necessary to make room, as a preliminary step.

The risk of hemorrhage is one of the great objections to this operation, and later on we shall describe another procedure, which is preferred by many, in which the knife is supplanted by other and bloodless instruments. It is no doubt true, as Allingham says, that the deep dorsal incision is the key to the operation, and greatly facilitates the securing of bleeding vessels; yet the hemorrhage may be so great as to impede the operator and endanger the life of the patient. It will be seen that at every step in this operation union by first intention is aimed at, and Lister's methods are carefully followed. If the elements of success in Listerism are, as I believe, cleanliness and drainage, these are certainly better met by a deep posterior wound, which is left open and syringed out frequently, than by carefully closing that safety-valve with catgut sutures and inserting a drainage-tube. It will also be observed that the bowel is always brought down and stitched to the free edge below. To do this much dissecting is necessary, and but little permanent good is gained, as the stitches soon tear out. Of the freedom with which the peritoneum is opened, and of the operation in general, as practised by the German surgeons for cases of the most advanced disease, we shall speak later.

Maisonneuve described, in *L'Union médicale* of 1860, an operation which he named the *procédé de la ligature extemporanée*, and which differs from the preceding in being almost entirely bloodless, although it differs little from the operation previously described by Chassaignac under the name of *l'écrasement linéaire*. In the latter the rectum is divided into two lateral halves by the chain *écraseur*, and each half of the disease is then attacked in the same way and removed. In the operation as done by Maissonneuve a strong cord is substituted for the chain, and the disease is removed in the following manner: the skin and subcutaneous tissue are divided by a circular incision which completely surrounds the anus. The operator is provided with several strong curved needles, each of which is to be threaded through the point as often as used, with a strong silk ligature about a foot in length. One of the needles with the ligature in its point is then passed from the external incision into the bowel above the growth, going wide of the gut to clear the tumor. The loop of string in the eye of the needle is seized within the rectum and drawn out of the anus, while the needle is drawn back out of its own track. The result of this is a double uncut ligature, passing from the point where the needle entered the external incision, outside of the tumor, into the rectum above it, and then out of the anus; and this manœuvre is repeated eight or nine times at points around the circumference of the anus equidistant from each other. A strong whip-cord or bow-string is the next requisite, about two yards long, and to this all the loops hanging from the anus are attached at points nine inches distant from each other. Each of the original ligatures is then withdrawn by the same course it entered, carrying a loop of the whip-cord with it. When all are drawn out, the rectum above the disease is surrounded by a series of loops of strong cord, and the ends of each loop hang out from the original incision. The ends are then attached to an écraseur, and each loop made to cut its way out in turn. After all have been cut out, the lower end of the bowel and the diseased mass are of necessity completely separated from their attachments.

The operation performed by Cripps * is a modification of the two preceding ones, and would seem to possess several advantages in facility of performance. The preliminary dorsal incision is made from within outward, by passing a strong curved bistoury into the rectum, bringing its point through the skin at the lip of the coccyx, and cutting all the intervening tissue. The buttock is then drawn away from the anus to put the tissues on the stretch, and a lateral incision made from the preliminary cut behind, around the rectum, to the median line in front. The site of this incision, whether inside or outside the anus, will depend upon the location of the disease, and whether or not the anus is implicated. The cut itself should be made boldly, and deep enough to reach well into the fat of the ischio-rectal fossa. The forefinger in this incision will readily separate the bowel from the surrounding tissue, except at the attachment of the levator ani muscle, which should be divided with the knife or scissors. A piece of sponge is pressed into this cut to restrain the bleeding, while the opposite side is treated in the same way. The anterior connections give more difficulty, and the dissection in the male is aided by having a sound in the urethra. The knife and scissors replace the finger in this part of the operation. When the dissection has been carried to a point above the disease, the bowel is drawn down, and held while the wire écraseur is passed over it, and the section made at the required level. After this there may be free, but seldom serious, hemorrhage. The vessels divided in the first steps of the operation all come from the wall of the bowel, and, if ligatured when first cut, are again opened with the écraseur. When the disease is located to one side of the bowel the operation is modified accordingly. The preliminary dorsal cut is the same, and the lateral incision is made on the affected side. At the farther end of this lateral incision, away from the dorsal one, a needle carrying a cord in its point is passed around the disease and into the rectum above it. The loop of cord is brought out of the anus, attached to the chain of the écraseur, and withdrawn as it entered. The chain is then made to cut its way out, and a rectangular piece of the rectum is thus included between two longitudinal incisions, one posterior with the knife and one lateral with the chain. In this rectangle is the cancer, and it is dissected up-

* Cancer of the Rectum. London, 1880.

ward from below, and separated above by again using the écraseur.

Instead of the chain or wire écraseur, the wire of the galvanic cautery may be used, heated to a dull red, and not a white heat, if the desire is to avoid hemorrhage. Or, again, instead of the wire the galvanic cautery knife may be used, and the operation performed with bloodless incisions. This is the operation favored by Verneuil. The rectum is first divided into lateral halves with the écraseur, as in the method of Chassaignac, the cut dividing both the anterior and posterior walls. Then with the galvanic cautery blade the lateral halves are separated from their attachments stroke by stroke, until a point is reached above the level of the disease. The chain is again slipped over the end of each, and the final section made.

An ingenious and simple method applicable to certain cases has been recorded by Emmet.* The growth in the case in which it was used was an epithelioma the size of a hen's egg, situated on the posterior wall of the rectum an inch above the sphincter, with considerable surrounding infiltration. The sphincter was stretched, and the mass seized with a double tenaculum and drawn well down by an assistant. "A steel grooved director, as the most convenient instrument for the purpose, was pushed through the skin in front of the coccyx and just behind the outer edge of the sphincter, into the cellular tissue of the pelvis, and then made to puncture the rectum, in healthy tissue, just beyond the upper edge of the tumor. The end was turned out of the gut, and pushed far enough forward to rest on the perineum while the other end was over the coccyx. Then a second director was pushed around from the outer side of the muscle on one side, through the cellular tissue into the rectum, across to the other side, through the cellular tissue and skin again to the opposite side of the muscle. So that the mass, with a portion of the rectum above, was now brought through the anus and fixed by the two directors, which had been passed behind the mass at right angles to each other, with their ends resting outside on the soft parts. The chain of an écraseur was placed behind these two instruments and slowly tightened till the whole mass, as transfixed, was cut through along the course of the directors. By this means I removed the entire sphincter muscle, about three inches of the posterior wall of the rectum, and about an inch and a half of the rectal surface of the recto-vaginal septum. The immediate result was a most formidable opening in the connective tissue of the pelvis, about three inches in diameter, and cone-shaped from below."

Dr. Rouset has recently called attention to a simple method of avoiding a wound of the sphincter, which is applicable to some of the slighter cases. A curved incision is made parallel with the outer border of the sphincter, and on a line with its outer limit. By introducing the finger through the rectum, the growth may be everted through this incision, and removed with the part of the rectal wall to which it is adherent.

Perhaps, as Molliere is inclined to believe, the best of all the operations we have spoken of is the combination of the écraseur and galvanic cautery knife, as used by Verneuil. But the operator is at liberty to choose from among them all the one he considers easiest of performance, and most free from the risk of hemorrhage, or of wounding surrounding parts.

* Principles and Practice of Gynæcology. Ed. 1879.
† Lancet, Oct. 2, 1880.

Regarding the immediate dangers of the operation, the first thing to be feared is hemorrhage, and the second, a wound of the peritoneum. Allingham says he has learned not to fear hemorrhage in operation on the rectum; and yet he warns against wounding the "middle hemorrhoidal (sacral?) artery" by approaching too near the sacrum; an accident which has occurred to himself, and which was followed by so free and so sudden a gush of blood as to convince him that in a weak patient it might easily have been fatal. The arterial supply to these tumors is often very free, and a spirting vessel four inches up the rectum is not an easy thing to secure in spite of the preliminary incision. I know of but one case in which death is said to have been due directly to the hemorrhage, although in many it is reported to have been very profuse, and no doubt contributed to the fatal result which followed in the course of the first few days.

A wound of the peritoneum is not an uncommon accident attending the operation, although it is one to be greatly deplored, and which has contributed more to swell the list of fatal results than any other. The deaths from this cause alone nearly equal those from all others combined; and whatever may be said of the impunity with which this serous cavity may be opened in other parts of the body, does not seem to apply here, for there are few cases recorded in which the accident has not ended fatally. A wound into the vagina, though always to be avoided when possible, may often be necessary in order to fully remove the disease.

When the fistula thus made is not too extensive, it may be closed immediately after the operation. If large, it must be left. A wound of the urethra in the male, when slight, is to be treated as though the patient had submitted to an external urethrotomy, by the frequent passage of the sound, to prevent contraction. When a large piece has been taken from the urethral wall a permanent recto-urethral fistula is the necessary result, though the danger of fatal inflammatory action is greatly increased, from the presence of the urine in the rectal wound. As for the cases reported by Nussbaum and others, in which the whole neck of the bladder, the greater part of the prostate, and the seminal vesicles have been removed, and the patients have lived for years in comfort, they are merely curiosities of literature. That such a thing may happen has been proved, but that the operation should ever be undertaken in any case where such a result is necessary for the entire removal of the disease, has yet to be proved.

After peritonitis, the most frequent causes of death are blood-poisoning and deep pelvic inflammation.* To account for this, we have only to remember the free venous supply of the rectum, the extent of the wound, and the lax cellular tissue filling the pelvis. It has happened to good surgeons that a patient has died of diffuse pelvic inflammation after a simple operation for fistula in ano. How much greater, then, must be the danger in an extensive operation such as is now under consideration. The best way to avoid such an accident has already been pointed out—leaving the wound open for the free escape of fluids, and the frequent use of disinfecting fluids injected into all its pockets and sacs.

Regarding the ultimate condition of the rectum in case of recovery from the operation, stricture to a troublesome extent is very rare. In one case, re-

* See "An Analysis of One Hundred and Forty Cases of Excision of Cancer of the Rectum," by the author, New York Med. Journal, December, 1880.

ported by Verneuil, a special plastic operation was performed to relieve this condition, an account of which may be found in the work of Marchand.* The opposite condition of incontinence is much more common, but it is no contraindication to the operation, because in the great majority of cases it is no more marked than after the only other surgical procedure applicable—lumbar colotomy. As a fact, in a very large proportion of cases the incontinence is not sufficient to cause any great amount of trouble, the patient being able to keep himself clean and avoid accidents by immediately attending to the call of nature as soon as felt. Only one element in the act of defecation has been removed—the sphincter. There are many others, so that, though the patient may not be able to resist the call to empty the bowel, there is still a call, and a certain amount of time to attend to it, except in cases of diarrhœa and fluid motions. In a few cases there will be a constantly unconscious discharge, which can only be met by the wearing of a bandage or apparatus.

The operation of excision has not yet been accepted by the entire profession as the best means of treating those cases of cancer of the rectum to which it is manifestly most applicable. By American surgeons, as a rule, colotomy is considered preferable, as giving greater relief, and more surely staying the progress of the growth. Excision can never be judged in comparison with colotomy, being applicable properly only to an entirely different class of cases. It must be judged in the light of actual experience of results in those cases to which it is best adapted. What are those cases? The Germans have apparently no limits to its applicability. They perform it in cases of the most extensive disease, opening the peritoneum, exsecting the sacrum, when necessary to reach its upper limit, and removing the prostate and base of the bladder when they are implicated, balancing the risk of immediate death from the operation against the chance of radical cure, or prolonged immunity from return. Conservative surgeons will hesitate long before accepting this view, for, although very satisfactory results have been obtained in such cases, they can hardly be considered other than exceptional, and a study of cases shows that the frequency of the fatal result is in direct proportion to the extent of the operation attempted. The rules for the selection of cases laid down by Lisfranc were these: when the bowel is movable, in other words, when the disease has not involved surrounding parts, the operation should be undertaken. When, on the other hand, the disease is more extensive, and reaches higher, he leaves the question to be decided by future experience. I believe that experience has now decided against it. In deciding for or against the operation, an examination of the glands in the hollow of the sacrum and in the loins is of great value, for these receive their lymph directly from the rectum, and may be enlarged, while those in the groin, which are supplied from the skin around the anus, may still be uninvolved. Although the hope of radical cure is but slight, there is still some chance of such a result; but the operation, when done at all, is generally undertaken merely as a palliative measure. Labbé, in a recent article,† rather argues against it, on the ground that, in ten of his cases, the average date of return was only ten months. This, I think, might be considered a very favorable result. Ten months of comfort, with the chance of painless death from return in the viscera, is certainly as good a result as any other treatment offers.

Progress of Medical Science.

Eye-Symptoms in Locomotor Ataxy.—Dr. J. Hughlings-Jackson read a paper before the Ophthalmological Society, London, December 9, 1880 (*Lancet*, December 18, 1880), in which three well-marked non-ocular tabetic symptoms were considered in connection with certain ocular symptoms. Twenty-five cases, in different stages, furnished the materials for the communication. Of these there were twelve of optic atrophy. In two there were also ocular paralyses, and in one a history of it; in nine there was Westphal's symptom. In one of the three, without this symptom, there had been no pains; gait was slightly ataxic. In the second there had been double vision ten years ago; there is now paresis of the left third nerve: this patient had pains, but his gait was normal. The third case was one of atrophy of one disk, with limitation of the field outward and downward; this patient saw green as gray, and red as reddish brown; he had pains, but his gait was good.

In one case, in which there was paralysis of those parts supplied by oculo-motor nerve-trunks, it was noticed that the patient had no positive symptom except Westphal's (tendon-reflex). This patient's pupils acted well to light and during accommodation; he had no pains of any sort anywhere. In one case, with normal pupils and Westphal's symptom, there had been paralysis of the third nerve. In one case of inactive pupils, with Westphal's symptom, there had been temporary double vision. In another, with inactive pupils and Westphal's symptom, paralysis of one sixth nerve. That condition of the pupil, observed by Hempel, Vincent, Erb, Hutchinson, and others, called the Argyll Robertson pupil, is a double condition, negative and positive, and in this way resembles the so-called disorder of co-ordination of locomotor movements. This symptom is not peculiar to tabes; it may be found in general paresis of alienists—at least, reflex pupillary immobility. Erb's diagram was exhibited to the society, which gave that physician's view of the central conditions corresponding to the double pupillary condition, and the following case was cited, which was considered a very rare one: A woman, aged twenty-six years, had sought advice, simply because her right pupil was larger than the left. It had been so for three years. The right pupil was dilated and absolutely motionless to light, and also during accommodation. Yet her ciliary accommodation on this side was perfect. She could read No. 1 Jaeger from fourteen inches up to five, or by effort to four. The field was perfect. The fundus was normal, except that the veins were large, and convoluted at the disk, probably physiological; the media were clear. Her sight with this eye was perfect. The pupil of the left eye was most active, and of normal size; the left disk was slightly paler than the right; the veins as on the right; macula normal; double slight limitation of nasal part of the field. She could read Jaeger No. 2 with the left eye, but the centre syllable of a long word seemed blurred. She seemed to be in perfect health, except for the ocular abnormalities mentioned. In testing her knees not the smallest trace

of the knee phenomenon could be found. There were no other symptoms of tabes. Erb has found the pupillary condition in patients who had no other nervous symptoms, as well as in nervous affections which could not be classed as tabes or as general paresis. Again, it is not said that the action of light may not be present in very well marked cases of tabes. Pagenstecher has recorded a case verifying this fact, and it has also been observed by Laidlaw Purves. Twenty-years ago Dr. Jackson had observed that many men who had "white atrophy" of the optic disks had also lightning pains in the legs; and later, on making a distinction as to the kind of atrophy, he concluded that the pains were a symptomatic link between "uncomplicated amaurosis" and locomotor ataxy. This atrophy is now more particularly described as gray degeneration, and is supposed by Charcot and others to be parenchymatous. The peculiar limitation of the field of vision in cases of the atrophy in tabes is significant when we consider that the developed disease is in great part one of the locomotor system. The limitation would seem to correspond roughly to certain ocular deviations from cerebellar disease, in the way that hemiopia does to lateral deviation of the eyes from cerebral disease. In all cases of optic atrophy we should inquire for the pains, and test the knees whether the gait be abnormal or not. The pains are often bridging symptoms between so-called uncomplicated amaurosis and tabes. Charcot says that, as far back as 1868, he pointed out that the great majority of women admitted into La Salpêtrière for amaurosis have, sooner or later, manifestations of tabes. He mentions one case in which the amaurosis preceded the pains ten years. Gowers has seen a case of tabes in which optic atrophy preceded other ataxic symptoms twenty years.

Esmarch's Bandage an Aid to Diagnosis in Simulated Contraction.—A case in point is narrated in the *St. Petersburg med. Woch.*, No. 25, 1880. A young soldier was said to have been afflicted with contracture of the flexors of his right leg for more than six years. Indications of existing disease were not seen. The affected extremity was enveloped with the elastic bandage and the constricting tube applied about the middle of the thigh. Without any feeling on the part of the patient, the leg was spontaneously extended, and could not afterward be made to assume its former position by voluntary efforts.—*Centralbl. f. Chir.*, December 18, 1880.

Extensive Carbuncle.—In the *British Medical Journal*, November 20, 1880, Dr. Joseph Hinton has reported a case of extensive carbuncle in a very stout old lady, who had been enjoying remarkably good health, being active, notwithstanding her age, which was nearly eighty. The whole of the nape of the neck was hard and brawny. By degrees, with nitrate of silver externally and potassa fusa placed in the little apertures, sloughing went on, and when at last the eschar had separated, the ulceration extended from ear to ear, some distance up the posterior part of the scalp, and down the upper portion of the back. Owing to the patient's size, the difficulties of dressing the neck were extreme. Everything that could support strength was given. The wound filled up slowly and the patient improved daily, when the case became complicated by a very large abscess on the outer part of the right gluteal region, and the patient finally succumbed eight months after the inception of the disease.

Amaurosis Following the Administration of Salicylate of Sodium.—A young lady, aged sixteen years, had been taking two drachms (8.0) of salicylate of soda within ten hours. The patient was under treatment for acute articular rheumatism. Complete blindness soon set in, together with enormous dilatation of the pupils. There was also torpor and somnolence. The sensibility of the conjunctiva and cornea remained unaltered. No internal ocular change. Deafness was also developed, and the cardiac action became much enfeebled. The pulse, too, was correspondingly weak. No trace of the salicylic salt was observed in the urine, neither was albumen found to be present. A profound slumber set in. Ten hours later the amaurosis disappeared, but mydriasis and deafness remained until the following day. Similar disturbances of vision have been reported by Buss, Fürbringer, and Schultze.—*Le Courrier médical*, January 8, 1881.

Treatment of the Lancinating Pains of Ataxia by Nerve-Stretching.—M. Charcot recently cited a case of locomotor ataxia, in which stretching of the sciatic nerve promptly alleviated suffering of long standing. The case was observed at the *Bicêtre* by M. Debove. It was one of those instances in which several of the symptoms usually witnessed in the spinal affection were wanting. The patient was about forty years of age, the son of an epileptic, and brother to several other epileptics. The most distressing symptom which he had consisted of violent and lancinating pains (douleurs fulgurantes) in both inferior extremities. Inco-ordination of muscular movements existed to a certain extent, preventing stationary support on his feet. In the arms, aching sensations were likewise present. He had been at the Bicêtre about a year, and was constantly bedridden. Hypodermics of morphia alone afforded him temporary relief. M. Gillette was therefore asked to try operative measures. The sciatic nerve of the left side was accordingly exposed and forcibly stretched with the forceps. An anæsthetic was not employed, nor did the operation appear to cause the patient much pain. Almost instantaneous relief followed this measure, and the pains have not returned.—*Gaz. des hôpitaux*, December 11, 1880.

Statistics of Mammary Cancer.—The immense material accumulated at the Vienna Pathological Institute has been utilized by Török and Wittelshöfer (*Archiv für klinische Chirurgie*, vol. xxv., 1880) in order to determine some questionable points in relation to the statistics of mammary carcinoma. In 72,000 bodies, of which autopsical records were made between the years 1817 to 1879, mammary cancer was found 366 times, or about in one-half per cent. of the cases. In about 30,000 female corpses the tumors were found in one per cent. of all cases. In perhaps eight of them sarcoma may have been present. Of 351 in which the location of the tumor was stated, 161 exhibited disease on the right side, 141 on the left, and 46 on both sides. Three times the disease was found in very old men. The age of the dead varied from twenty to ninety years; the majority of cases occurred between forty and seventy years. In 184 instances the patients had undergone operation; of this number, 105 were found without metastatic deposits. Of the 182 who had not been operated upon, only 41 were free from secondary nodules. Secondary local dissemination was frequently found in the adjoining integument, muscles, glands, pleuræ. Very rarely distant organs were found to have become involved by local extension. Thus, in the pericardi-

um, peritoneum, and liver, such secondary deposits were seen only in two cases of each. Secondary metastatic neoplasms, however, were frequent. In the lymph-glands they were found 192 times, in the respiratory organs 132, in the organs of digestion 139; of which number 127 belonged to the liver.—*Centralbl. für Chir.*, December 18, 1880.

Laryngeal Tubes in Operations Within the Buccal Cavity.—One of the dangers attending operations in the mouth and pharynx is the entrance of blood into the respiratory passages. In many such cases it has been deemed necessary or advisable to perform a preliminary tracheotomy. Verneuil (*Gaz. des hôpit.*, December 4, 11, 1880) recently had occasion to excise the superior maxilla for epithelioma. As a precautionary measure, to avoid a possible flow of blood into the trachea, Dr. Krishaber had been requested to pass a tube into the patient's larynx. This manipulation had been attempted several days previously, but, the patient not being under the influence of an anæsthetic, the presence of the instrument in his larynx caused such terror that the tube had to be quickly withdrawn. On the day of the operation, however, the patient was anæsthetized and the canula was then readily passed into the trachea, without causing any embarrassment of respiration. Anæsthesia was then kept up by giving chloroform through the tube, and the operation was thus rendered an easy one. Bouchut had long ago advocated this measure for other purposes, and had pointed out its easy performance and comparative innocuousness. In order to secure the perfect adaptation of the instrument to the walls of the trachea, an inflatable membrane is adjusted to the canula. This may be filled with water to any desired degree, thus effecting a perfect closure of the air-passages. (The action of this instrument appears to be similar to that of Trendelenburg's tampon-canula, and will, therefore, probably share with that apparatus its inconveniences, and above all, its lack of reliability. A more efficient canula for similar purposes has lately been devised by Dr. Gerster, of this city, and will be described in a future number of the Record.)

Symptoms Simulating Strangulation in Inflammation of Empty Hernial Sacs.—At a meeting of the Vienna Physicians' Society (*Mittheil. des Wiener Med. Doct. Colleg.*, vol. vi., No. 26, December 2, 1880), Dr. Englisch read a paper with the above title. Forty cases had been collected, and in thirty herniotomy had been performed. His own experience extended to six cases, of which number four had concerned women. In the latter cases femoral hernia was observed exclusively. If, in consequence of some irritation or traumatism, the peritoneum of the sac became inflamed, symptoms of strangulation would be developed, even if the sac had no intestinal or omental contents. The protrusion would first of all become exquisitely painful, rapidly increase in size, and become tense. In some few instances the augmentation in volume had been slow.

The quality and extent of the pain might aid differential diagnosis, without, however, being so characteristic as to exclude the possibility of error. In actual strangulation, the most intense pain would be felt at the constricting ring, and thence extend into the abdomen. If an empty sac became inflamed, the hernial protrusion would be most tender, and pain might be absent at the ring. This symptom was, therefore, not reliable in all instances, nor would such differences be found in cases of longer standing. The condition of the integument afforded a better clue to differential diagnosis. Provided rude taxis had not been resorted to, the skin over a strangulated hernia would be found unaltered and freely movable. In inflammatory action about an empty sac, the subcutaneous tissue would become infiltrated, the skin itself would grow red, and after one or two days would adhere to the subjacent tissues.

Vomiting was not a characteristic symptom. It might get progressively worse in inflammation of an empty sac. Constipation was equally unreliable, although there was no mechanical obstruction; cases had been observed in which enemata and purgatives had produced no action of the bowels, not even the escape of flatus. The condition of the hernial tumor was not a trustworthy guide to go by. In inflammation of the empty sac it might be impossible to effect a reduction in the size of the protrusion, just as in true strangulation. As regards the temperature of the body, it might materially aid differential diagnosis. In strangulated hernia a febrile movement might be postponed to the third or even fifth day, whereas in inflammation of an empty sac an early rise of temperature took place.

In most cases of the latter description the patients belonged to the female sex. This was owing to the fact that in women crural hernia was more frequent, this variety being, also, the one which oftener led to inflammation of the empty sac. No single symptom, therefore, could be safely relied upon, and even the conjoined presence of several might still lead to a wrong diagnosis. Surgeons were incidentally cautioned against pumping air into the bowels in giving injections, because the re-escape of such air might mislead one to assume the presence of flatus.

Sulphide of Calcium in Inflammatory and Suppurative Processes about the Ear and Throat.—At a meeting of the St. Louis Medico-Chirurgical Society, Dr. Todd, in discussing the above subject, stated that he had administered this medicine in the case of a child about eleven years old, who was suffering intense pain from suppuration of one of the ears. There was also a great deal of swelling about the ear and some of the neighboring glands. Under doses of one-twentieth of a grain, given every two hours, the pain was relieved in a most marked manner. Dr. Spencer, in referring to the use of this drug, stated that in his experience, after giving it a fair trial in some forty-five cases of furuncular inflammation, together with suppurative process in the middle ear, he could not see that it had in any instance either shortened a case or influenced it in any way. Dr. Glasgow reported that he had treated several suppurative cases successfully. One of them, a case of tonsillitis, where the pain was intense, was greatly benefited by the use of one-quarter of a grain every two hours. Others, however, who reported their experience to the society, had failed to obtain results similar to those of Dr. Glasgow.—*American Journal of Otology*, January, 1881.

Chlorate of Potassium, and the Increase of Nephritis.—In his work on diphtheria, Dr. A. Jacobi says that chlorate of potassium, or sodium, is used more probably than any other drug. It is used domestically, and is then not weighed out, but taken indiscriminately. Acute nephritis, probably, and chronic nephritis, certainly, is oftener met with now than it was formerly. Dr. A. Jacobi is inclined to think that the chlorates are partly to blame for this increase in nephritis. Such a view is rather a transcendental one.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 12, 1881.

THE GENERAL PRACTITIONER.

In these days, when the treatment of the diseases of almost every organ is being appropriated by specialists, the general practitioner finds his former field of usefulness becoming comparatively small and insignificant. In fact, he is often brought to the point of asking what is left for him. Many times he feels that he is the mere go-between for the patient who may wish trustworthy information concerning the specialist to be consulted. A probable reason for this is that comparatively few men, at least in our larger cities, care to be general practitioners, deeming that the latter class are particularly exposed to the luck of such as are hindmost in the race for fame and fortune. Certain it is that the family doctor is not in the majority, as he should be, in our larger cities. His type is still to be found, however, in the rural districts. It was an agreeable surprise to the members of the State Society, at their recent banquet, to hear the claims of the general practitioner advocated in the response by one of the rural members to the toast of "The country practitioner." Although the subject received the humorous treatment of a post-prandial effort, the real truth was very satisfactorily brought out. When the speaker claimed that the practitioner of the country was a man of varied responsibilities, a creature of many emergencies, and an individual who needed all his brains, he not only spoke the truth concerning a representative class of medical men, but was, perhaps, unconsciously sarcastic toward many physicians who do not live in the country and do not attend to family business.

At all events, he used his opportunities for retaliation upon such as supposed that the mere country practitioner was not a useful member in the church medical. None of the members needed to be told that the country practitioner was unable to call a consultation when he found a patient "in the last house on the road," in the dead of night, "with his throat grown shut," and that the doctor must make use of what brains he had, or the patient would die. And yet, underneath all the merriment which this and other droll allusions called forth, there was an eloquent plea for the general practitioner—"the medical man of brains"—who is found not only in every portion of our State, but who, as the type of the "family doctor," is scattered over all parts of our country. The circumstances which surround him are so different and so varied that he is forced to rely almost entirely upon his own efforts in treating every case that presents itself. With the full appreciation of what is required of him, he is not at liberty to decline attendance upon this or that case merely because he wishes to be simply a physician or wholly a surgeon. He is just as likely, without warning as to the nature of the case, to be summoned miles from his home in the darkness of the darkest night, over roads almost impassable, to operate upon a strangulated hernia, possibly with a razor or sharpened jack-knife, and by the uncertain light of a tallow dip, as he is the day following to attend upon a case of indigestion in the family of his wealthier neighbor. His obstetric cases are to be managed by himself, and if any complication exists to endanger the life of his patient, upon him alone, in most cases, devolves the responsibility of acting on the spot.

It is seldom that the general practitioner has a more effective advocate than was the respondent of the toast. The avowed disposition of "the plain doctor" to appropriate all that he believed was good from the expert, merely because the latter took so much pleasure in imparting information, was a delicate stroke of irony at the expense of some of the gentlemen who present papers at similar organizations, and who so often fail in giving a practical turn to their observations. Altogether it is comforting to know that the general practitioner is not yet extinct, that he has brains enough to appreciate his opportunities, and enough knowledge of his profession to discharge all his various and responsible duties to the sick with credit to himself and with benefit to his race.

THE RECENT MEETING OF THE STATE SOCIETY.

The recent meeting of the Medical Society of the State of New York was a very satisfactory one. Although the attendance was not as large as might have been expected, the proceedings—thanks to Dr. Bailey, the President—were varied and interesting, and much important business was transacted. The papers were not as numerous as on former occasions, but this was comparatively advantageous, inasmuch as it allowed more time for discussion. They were practical in character, and the variety of their subjects gave great interest to the proceedings. As will be seen by a reference to our report elsewhere, many matters relating to medical legislation were discussed

and acted upon. Not the least of these were the appointment of a committee to revise the code, and the recommendation for the abolition of the office of coroner. The choice of President for the ensuing year gave great satisfaction to the members. The honor is well deserved, and its bestowal upon Dr. Jacobi reflects credit on the society. The election of Dr. Govan as Vice-President was also a happy one, and was a reward for long and faithful services.

THE PHENOMENA OF TRANCE.

Several weeks ago we referred to a revival of interest in the various phenomena which have gone under the names of mesmerism, hypnotism, nervous sleep, trance, etc. The subject continues to excite increased interest in England and this country, as well as in Germany and France. It is receiving more attention also from scientific men than ever before. In this city, Dr. Geo. M. Beard has spent a great deal of time and labor in studying the various phases of the trance state, and, largely through him, many members of the profession here have seen and been convinced of the genuineness of phenomena heretofore uncredited. Although the subject of mesmerism, to adopt the more familiar term, is an old one, even in its scientific aspects, it has lately received enough additional light and excited enough scientific interest to justify a fuller account of it than we have yet given.

Of the various names applied to the phenomena in question, that of trance, adopted by Dr. Beard, is perhaps as good as any. The condition of trance is one that affects lower animals as well as man. Crabs, fishes, frogs, birds, and the various quadrupeds can all be brought under it. "Rarey's method" of horse-taming was to put the animal in a trance. This trance condition in these lower animals, however, is less stable and produces much less interesting phenomena than it does in man.

Among human beings the persons most easily affected are those, speaking broadly, of nervous or emotional temperament. In individuals who have vigorous or well-disciplined minds, trance is, as a rule, induced with difficulty or not at all. The highest manifestations of the state probably occur oftenest in women. There is hardly any age when the phenomena may not be developed, but they are more frequently observed in the first half of life, and may decline in force as the person grows older or loses health. A curious fact, noted by certain travelling mesmerists, is that there are more persons who are susceptible to trance in dry and elevated localities than there are in places near the sea-shore. The "subjects" are very numerous in Minnesota, for example, but scarcely to be found at all on Cape Cod.

There has been nothing in the recent studies of trance which throws a ray more of light upon the physiology of its production. It is shown, however, that all the old theories regarding it cannot be maintained. The fact is now well established that "passes" and bright objects are not absolutely necessary to induce trance, but that the patient can go into it of his own accord. The theory advocated by Dr. Tuke, that it depends on changes in the vascular supply of the brain, is without any support whatever in facts. There are two well-marked phenomena in the trance state which every theory must take into account. These are: a suspension of the volitional power of the subject, leaving it at the mercy of every outside suggestion; and an exaltation of certain functions or senses, with an inhibition more or less complete of the rest. In certain forms of trance, such as somnambulism, the exaltation is very slight, if present at all, while the inhibition affects nearly all the higher cerebral centres, leaving the subject for the most part an automaton under the control of the basal ganglia and cord. On the other hand, in some of the intellectual phenomena of trance, all the mental power or nervous force of the individual is concentrated in some particular direction. The subject is for the time a visionist, a poet, an orator, or a mathematician. He illustrates the supremacy of intellectual or sensory concentration. All of the other powers of mind or of special or general sense are suspended. This theory of "exaltation" propounded some time ago by Dr. Beard, is the most rational and widely applicable of any with which we are acquainted. It does not, however, carry us to the bottom of the matter, or explain all the peculiarities of this abnormal state.

The simplest of the phenomena of trance are those which affect motion and sensation; increased muscular power, paralysis, catalepsy, or absolute rigidity of single muscles, or of half or all of the body, may be induced. Areas of anæsthesia may appear, and these may be as small as a pin's point or involving accurately half the body. A patient who stands without flinching the pricking of pins, pinching, or the red-hot iron, in a moment may be brought out of his trance, and then begins to feel the now painful part.

It is in the exaltation, during trance, of the special senses, or of special intellectual functions, that the most remarkable phenomena appear. The entranced subject speaks with all the power of an intense and earnest concentration, upon any subject suggested, provided that subject be one with which the speaker has, at least, some slight knowledge, for the trance brings out nothing which was not in the individual at first. Two very interesting facts are developed in connection with this speaking. One is an exaltation of the capacity to measure time. If a half-dozen persons are mesmerized and told to speak each on different subjects for different periods of time, they will almost always stop speaking within thirty seconds or less of

the time specified. Again, there are peculiar reflexes by which speech is interrupted or set going. Thus, if, when a trance-speaker is in the full tide of an impassioned harangue, pressure be made over the seventh cervical vertebra, aphonia will be produced, there being movements of articulation with the tongue and lips, but no sound from the larynx. A touch upon the cheek, over the point of emergence of the seventh nerve, relieves the aphonia, and the subject speaks again. The same interruptions can be produced by passes up and down in front of the face, and by reflex excitations of other parts of the body. The two points mentioned, however, are considered to be those which are by far the most commonly and easily affected. The increased intellectual power that may be attained in a trance-condition is very great. The emotional and imaginative faculties are those that, so far as we know, seem capable of the highest exaltation. A trance-poet in this city can turn out very fair poetry on almost any subject, at the rate of one hundred words a minute. The rhyme and rhythm are uniformly good, and the ideas are connected and often well expressed.

The state of trance has been called by Tuke "artificial insanity." Though this term is an exceedingly bad one, yet it is certain that an artificial insanity can be produced. A young woman who had, several years before, been rendered for a time insane, chiefly by the anxieties of school-teaching, was mesmerized. The associations of a school-room were then suggested; the subject at once felt all the old emotions come back, and in a few minutes was raving and maniacal. She was brought out of that condition with some difficulty.

In the exaltations of the special senses trance displays some very curious features. We have referred to this point to some extent in a previous article, but much more can be said about it.

If the ears are stopped with wax, and a number of watches, some of which are going and some not, are placed low down on the back of the neck, the trance-subject will tell which watch is ticking. Ordinarily a watch cannot be heard in that spot. German observers claim the same power of hearing over certain regions of the abdomen. Complete deafness to every noise except the voice of the mesmerizer seems to be produced without difficulty. Such a condition is, of course, only the deafness of intense abstraction.

By suitable manipulations the sense of vision may be remarkably affected. Strabismus, amblyopia, and color-blindness can be produced in one or both eyes. Examinations of the retina made on one occasion by Dr. Mittendorf failed to show any notable change in the vessels of that membrane. It is possible for the range of vision to be increased or shortened. Thus, a somewhat myopic person can in a trance read test-types at a greater distance than when he is in his normal state. A number of other modifications of this visual sense can be brought about. The power of seeing through translucent bodies, such as the eyelids and handkerchiefs, is one which few will believe in unless they have seen it. We present, in another column, an account of an experiment in this direction, which our readers can receive with such confidence as they choose.

We have not space to refer to the modifications in taste and smell which may be developed. They all illustrate the same law that a trance-subject will smell and taste, just as he will hear and see and think, anything whatever that is suggested to him.

We have described these phenomena at considerable length, without entering at all into the question of their genuineness. This, so far as we can learn, is not doubted by any who have practically investigated the subject.

THE ANNUAL REPORT OF THE MEDICAL DEPARTMENT OF THE ARMY.

The annual reports of the Medical Department of the Army always show much work accomplished that is of importance to the profession. That which is of most interest, of course, is the medical and surgical history of the war, and the collections in the Army Medical Museum. Regarding the former, we are told that much progress has been made with the concluding part of the surgical history. The fifth volume of the whole work is now going through the press. It is gratifying to learn, also, that a bill has been introduced into Congress, which authorizes the printing of an edition of 50,000 of the four volumes already published. This is to satisfy a constant demand for the work which is made upon the department by the profession in all parts of the country. As additional contributions to this work, it is stated that, through correspondence with medical officers in the civil war, from reports of pension examiners, and from medical journals and other publications, additional data have been obtained in 5,889 cases of injuries. One hundred and seventy-eight drawings and cuts have been prepared for the third surgical volume, and it is evident that no labor is spared to make the records of this history complete.

A catalogue of the specimens in the Army Medical Museum has been made during the past year. This shows that the total number of specimens now on hand is 22,096, and that 538 have been added during the past year. The microscopical section and that on comparative anatomy have received the most additions. In connection with the work in this museum, we learn that seventy-six negatives and 1,115 photographic prints of surgical subjects have been made. Besides this, accurate measurements of one hundred and forty-three human crania, and of twenty-two human skeletons have been made. The medical museum has long been one of the regular resorts of sight-seers in Washington, and that its attractions

continue to be appreciated is shown by the fact that 34,111 visitors registered their names during the year.

The medical library has, of course, been largely increased. It numbers now 51,500 volumes and 57,000 pamphlets. There were 2,500 volumes and 3,500 pamphlets added during the year. The edition of fifteen hundred copies of the first volume of the Index Catalogue was printed and sent out last summer. The first part of Volume II. has now gone to press, and an estimate has been forwarded for printing Volumes III. and IV. We have before expressed the hope, which every medical man must share, that Congress will grant the money for a speedy completion of this great work. The Surgeon-General states that both the museum and library are in a building which is not fire-proof, and which is surrounded by old and inflammable wooden structures. The experience of the past with the Smithsonian Institution and the Patent Office should lead the Government to supply what is earnestly recommended in the report before us—a fire-proof building for the many valuable and irreplaceable collections in the care of the medical department.

Regarding the condition of the medical staff, we learn that there are now on it, on active duty, one hundred and sixty officers, with eighteen more on ordinary or sick leave. There were one hundred and forty-four candidates for the position of assistant surgeon examined last year, of which number twenty-one were found qualified. The number of vacancies in the grade of assistant surgeon is now nine.

A Clinical Demonstration of the Accuracy of Cerebral Thermometry.—Professor Arata, of the University of Geneva, removed a tumor from the neck of a man aged fifty years, and was obliged to tie the right common carotid during the operation. Five hours later Professor Maragliano applied thermometers to the head and found the following temperatures: Frontal region, *right*, 35.9° C.; *left*, 37.6° C. Temporal region, *right*, 34.3° C.; *left*, 37.4° C. Occipital region, *right*, 36° C.; *left*, 36.2° C. Mean of mid-half, *right*, 35.4° C.; mean of mid-half, *left*, 37.1° C. Now, as the cerebral cortex in the frontal and parietal regions is irrigated by the anterior and middle cerebral arteries, both branches of the internal carotid, it is evident that ligature of the common carotid must have diminished their blood-supply, with a probable result of lowering temperature. On the other hand, the occipital lobes are nourished by the posterior cerebrals, branches of the vertebral, and their blood-supply and temperature we might infer would not be affected. The thermometrical readings and the changes in the blood-supply thus corresponded.

Mr. Frank Buckland died in London recently. He was a graduate of Oxford and of St. George's Hospital, being a fellow-student of Mr. Holmes. Mr. Buckland did not follow medicine long, but yielded to his fondness for natural history and zoology, in which branches his name is very familiar. He founded and edited *Land and Water*.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Seventy-Fifth Annual Meeting, held in Albany, February 1, 2, and 3, 1881.

Tuesday, February 1st—First Day—Morning Session.

The society met, pursuant to adjournment, in the city of Albany, at 10 o'clock A.M., and was called to order by the President, Dr. William H. Bailey, of Albany.

Prayer was offered by the Rev. Walton W. Battershall.

The President then delivered his

INAUGURAL ADDRESS.

After suitably expressing his indebtedness to the society for the distinguished honor conferred upon him by his selection for the high office of President, he went on to contrast the comparative ignorance and lack of harmony of seventy-five years ago with the present flourishing condition of the profession in our State. "The history of our society, if carefully written, would show a most creditable record, and it must ever be a matter of regret that the proceedings of the earlier meetings were not more fully recorded for preservation."

The increasing influence of the society was then alluded to, as well as kindred matters, showing its present creditable status and the encouraging promises for the future.

"Our annual volume is our biography—historical and professional, bequeathed to us from the fathers in the profession. Let us cherish it; let us, while we may, improve and enlarge its scope, and discourage any thought or suggestion of discontinuing it or impairing its usefulness."

The code of ethics was made to meet the necessities of early days, and undoubtedly served an admirable purpose then, besides having been comparatively useful since. But, in the progress of years and the marked advancement in medical science, the wants of the profession had greatly changed. He recommended, therefore, that the present code be materially revised—possibly a new one made more in harmony with the changed conditions of the profession toward each other and the public.

The registry law enacted in 1880 had its defects, yet it was beneficial in many ways. The law of 1872, relating to the examination of candidates for the degree of Doctor of Medicine, in Section 3 declared that such examination should be "according to each of the systems of practice represented by the several medical societies of this State." It had been decided by authority that such examination was to include *all* the systems recognized by law. This was a glaring defect, and he recommended that application be made to the Legislature to so amend this law that each school would be made responsible for its own faith and practice.

The education of the community as to the necessity of sanitary reform was next set forth, in which connection the good accomplished by the State Board of Health was pictured. He was indebted to the learned and experienced Secretary of the Board, Dr. Elisha Harris, for much information of its labors

and purposes. The system of collecting vital statistics was here alluded to, as also the registration and careful record of the causes of death.

The necessity of some such power as was delegated to the State Board was shown in the wide range of subjects embraced in the inquiries directed to its officers: the preventable sources of miasmatic diseases, pollution of wells and watercourses caused numerous complaints; diphtheria and scarlatina, many requests for advice; small-pox the greatest alarm. Invitations to make special investigations were frequent; also the demand for analyses. Local authorities asked counsel in sanitary matters. All this showed that the necessity for such supervision and control as was intrusted to this board was fully appreciated.

It was his sad duty to announce the death, last year, of the following members: Drs. H. K. Bellows, of Norwich, Chenango Co.; Edward R. Hun, of Albany; John V. Lansing, of Albany; Levi Moore, of Albany; Charles A. Robertson, of Albany; Lake G. Tafft, of Syracuse; John F. Whitbeck, of Rochester; William H. Price, of Phœnix.

Suitable obituaries would be prepared and presented to the society, according to the usual custom.

On motion by Dr. A. Van Derveer, of Albany, the President's address was referred to a special committee.

ANNOUNCEMENTS OF COMMITTEES.

The following committees were then announced by the President:

Committee on Credentials.—Drs. B. F. Sherman, of Ogdensburg, Geo. W. Cook, of Otego, and Charles E. Willard, of Catskill.

Business Committee.—Drs. A. Van Derveer, of Albany, Wm. W. Potter, of Batavia, Charles L. Stiles, of Owego.

COMMUNICATIONS FROM COUNTY MEDICAL SOCIETIES.

Dr. Johnson, of New York, presented a communication from the Medical Society of the County of New York relative to the revision of the Code of Ethics.

On motion by Dr. Piffard, this communication was laid upon the table. A second communication was also tabled. Another communication was referred to the Committee on Legislation.

THE REPORT OF THE COMMITTEE ON BY-LAWS

was then received and its recommendations adopted.

MEMBERS BY INVITATION.

The following gentlemen were proposed by Dr. S. B. Ward, and duly elected: Drs. O. D. Pomeroy, of New York; De La Mater, of Schenectady County; E. A. Bartlett, of Albany; John M. Bigelow, of Albany; S. R. Morrow, of Albany. Dr. Clarkson T. Collins, Delegate from the Massachusetts State Medical Society, was introduced to the society, and invited to a seat. Later the following were elected: Drs. C. S. Merrill, of Albany; C. J. Hull, of Norway; C. W. Hamlin, of Middleville; P. B. Collier, of Albany; John B. Stonehouse, of Albany; Lorenzo Hale and S. O. Vander Poel, Jr., both of Albany; also, Drs. R. H. Sabin, Edward E. Brown, and Amos Fowler, of Albany County; C. L. Squire, of Elmira; H. J. Fellowes, of Albany; F. M. Curtis, of Albany; I. S. Munson, of New York; J. W. Gould, of Albany; John Thompson, of Albany; D. H. Cook, of Albany; Wm. Geoghan, of Albany; M. R. C. Peck, Theo. P. Bailey, and Franklin Townsend, of Albany; Edmund C. Wendt, of New York City; William Hailes, Jr., of Albany; A. B. Husted, W. H. Murray, H. S. Case, all of Albany; L. A. Tourtellot, of Oneida County; W. P. Seymour, of Rensselaer.

On motion by Dr. Squibb, it was resolved that two members be appointed to act as a

DELEGATION TO THE INTERNATIONAL CONGRESS OF MEDICINE,

to meet in London in August next; two alternates to be likewise named by the nominating committee.

SYMPATHETIC NEURO-RETINITIS.

Dr. David Webster, of New York, read a paper upon the above subject. It will appear in a future number of the Record.

Dr. Pooley, of New York, remarked that, in addition to the two cases referred to by Dr. Webster, he had quite recently seen still another instance of this disease. The case was that of a boy, who was at present under the care of Dr. H. Knapp, at the Ophthalmic and Aural Institute. The patient had received a wound of the sclero-corneal margin, associated with prolapse of the iris. Although the protruding iris was abscissed, some plastic irido-cyclitis ensued.

In the other eye, as well as in the injured one, a very marked neuro-retinitis had developed. The case was still under treatment, and the injured eye had not been enucleated. In the secondarily affected eye there was no inflammation of the uveal tract. Dr. Pooley thought it important to make a strong distinction between a neuro-retinitis, which was only one of the symptoms present in sympathetic irido-cyclitis, and neuro-retinitis pure and simple. In the first instance the affection of the optic disk and retina was difficult to determine because of the haziness of the vitreous, and, when it really did exist, might be an extension of the inflammatory process by continuity along the uveal tract. While in the second, especially where neuro-retinitis was seen in the injured eye, it was not impossible that the propagation was by way of the optic tract.

Would it not be best to call only the latter class sympathetic neuro-retinitis?

Dr. N. L. Snow, of Albany, then read a paper entitled

LITHOTRIPSY WITH ENTIRE REMOVAL OF FRAGMENTS AT SAME SITTING, BY BIGELOW'S ASPIRATOR.

After a review of the history of the operation, the doctor reported the following case:

Robert A——, an American by birth; aged fifty-three years; family history good; first noticed trouble in micturition in spring of 1879. In November of same year chronic cystitis was diagnosed and treatment therefor instituted during the following winter. In October, 1880, was examined with Thompson's short curved sound, and a small stone detected, which rapidly increased in size until December, when the operation was performed. The time occupied in the operation was thirty minutes; weight of fragments, eighty grains. On January 6th, ten days after the operation, the patient was able to attend to business.

Dr. O. D. Pomeroy, of New York, an invited guest, demonstrated the mode of application of his modified aural and throat mirror; also of an improved ear-syringe, representing a modification of Toynbee's instrument.

On motion by Dr. Webster, the communication was referred to the Committee on Publication.

Dr. A. McLane Hamilton, of New York, read a paper

UPON THE SIGNIFICANCE OF FACIAL HAIRY GROWTHS AMONG INSANE WOMEN.

It will appear in a subsequent number of the Record.

Dr. Charles S. Bull, of New York, then read a paper entitled

CONTRIBUTION TO THE PATHOLOGY OF ORBITAL TUMORS, BEING A STUDY OF THE SECONDARY PROCESSES IN THE PERIOSTEUM AND BONES OF THE ORBIT AND VICINITY.

The following is a *résumé* of his conclusions:

Such cases were not fit subjects for operative procedures. When the periosteum of the orbit or the orbital tissue were involved, it did not seem possible to remove all the growth, owing to the nature of the parts. Any mass of cellular infiltration, no matter how small, became at once a starting-point for more rapid growth than before. With each operation there followed an increased rapidity of growth, the tumor showing a tendency to change from pure sarcoma to myxo-sarcoma. When once the bones of the orbit were involved, he did not think that any further operative interference should be attempted. The rapidity of growth among the small bones of the face and base of the skull, and their disintegration by infiltration with the large sarcoma-cells, was very marked, especially in the case of the ethmoid and sphenoid bones. The small amount of good obtained by an operation was but temporary, and was far out-weighed by the dangers of the operation, the severity of reaction, and the rapid recurrence of the growth.

Dr. Pooley, of New York, said that, in confirmation of a statement made by Dr. Bull, *i.e.*, that a sarcoma, when encapsulated was less likely to recur than when free, he would like to report a case in point. A patient under his care in Charity Hospital had an orbital tumor which displaced the eye outward and downward. The eye itself was unaffected. It was proposed to remove the growth without sacrificing the eye, but the patient would not submit to an operation. It was not until about two years later that the tumor had so far progressed as to destroy the eye. The eyeball and tumor were then both removed, when the tumor, which was very easily enucleated, was found to be encapsulated.

Dr. L. D. Bulkley, of New York, read a paper entitled

FAVUS AND ITS TREATMENT BY A NEW METHOD OF DEPILATION.

After detailing his experience with several methods which had proved unsatisfactory, he advised the preparation of sticks of various sizes, from one-fourth to three-fourths of an inch in diameter, and cut off in lengths of two or three inches.

The formula was as follows: ℞. Ceræ flavæ, three drachms; laccæ in tabulis, four drachms; resinæ, six drachms; picis Burgundicæ, ten drachms; gummi Dammar, one and a half ounces. By the use of such differently sized sticks, they could be applied to affected surfaces of various sizes.

"They melt at a comparatively low temperature, and yet are hard at that of the body. The hair should be cropped short over the part to be treated, and, as the stick is applied, a slight rotary or twisting motion is given to it. After it has been applied for several minutes, it is removed by bending it over and drawing the hairs in succession. The hairs thus left in the stick are burned off. It is sometimes necessary to repeat the operation. This operation does not work so well in ringworm of the scalp, because the result of the action of the parasite on the hairs is to render them so brittle that they very easily break off."

Dr. E. R. Squibb called attention to the alleged anæsthetic effects of carbolic acid, which he and others had been able to verify.

Dr. H. G. Piffard said the first attempt at successful treatment of favus had been inaugurated by a couple of quacks in Paris. Dr. Keyes had brought a stick of cosmetic from Paris, which was found to possess powers of depilation. Similar sticks he now used, and preferred to the method of depilation by the forceps, in cases of sycosis.

Dr. Jewett, of Canandaigua, remarked that simple shaving of the scalp had, in his experience, cured most cases of ringworm.

Dr. Piffard stated that shaving had been given a large and extended trial, and had been pronounced in most cases a failure.

Dr. Bulkley, in closing the discussion, said that shaving was a well-known means of treatment, which was of service in recent cases, in connection with proper local measures. But shaving was by no means always curative, for, in the public institution to which he had referred, he had had this used in many of the forty cases of ringworm there under his care. These were shaved two or three times weekly, and even with varied local applications, the disease, in many instances, had lasted several months. It was of far greater value in recent cases than in those of long standing. But it was also of the greatest importance to differentiate between favus, or tinea favosa, caused by the parasite *achorion Schoenleinii*, and ordinary ringworm, tinea or herpes tonsurans, caused by the *trichophyton tonsurans*. The former extended deeply into the hairs, and caused destruction of the hair-follicles, resulting in cicatrices on which no hair could grow; whereas ringworm did not thus produce scars and permanent baldness. In ringworm more superficial treatment was sufficient, but in favus depilation was necessary, because of the deep penetration of the parasite, both in order to remove the affected hairs and to allow any remedy to reach down into the follicles.

PAPERS READ BY TITLE.

The following papers were then read by title, and referred to the Committee on Publication: "Obituary Notice of Dr. Daniel Golden Thomas," by Dr. Samuel G. Wolcott, of Utica; "Acute Primary Synovitis of the Hip," by Dr. V. P. Gibney, of New York; "Case of Fracture of Rib of Right Side—Perforation of Lung, with Emphysema of Chest and Colles' Fracture of Right Forearm—Perfect Recovery," by Dr. J. B. Graves, of Corning; "Obituary Note of Dr. J. V. Lansing, of Albany," by A. Van Derveer, M.D., of Albany.

The President announced that, in accordance with the plan adopted at the last annual meeting, the Committee of Arrangements had arranged for the annual dinner to be held at the Delevan House, on Wednesday evening, at the expense of the participants. The price of the tickets had been fixed at one dollar.

The society then adjourned to meet at 3 P.M.

FIRST DAY—AFTERNOON SESSION.

The society was called to order at 3 P.M., by the President, who later announced the following

COMMITTEE ON NOMINATIONS.

Dr. John P. Gray, member at large.

For First Senatorial District.—Dr. H. G. Piffard, of New York Co.

For Second Senatorial District.—Dr. William Govan, of Rockland Co.

For Third Senatorial District.—Dr. LeRoy McLean, of Rensselaer Co.

For Fourth Senatorial District.—Dr. L. C. Dodge, of Clinton Co.

For Fifth Senatorial District.—Dr. Charles G. Bacon, of Oswego Co.

For Sixth Senatorial District.—Dr. H. R. Rainsworth, of Steuben Co.

For Seventh Senatorial District.—Dr. Theo. Dimon, of Cayuga Co.

For Eighth Senatorial District.—Dr. W. W. Potter, of Genesee Co.

TREASURER'S REPORT.

D. CHAS. H. PORTER, of Albany, Treasurer, presented his annual report, which showed the receipts to have been $2,956.69; the disbursements $2,349.88; leaving an apparent balance of $606.81, of which $605 was dues paid in advance by societies and permanent members; thus, the actual balance was $1.81.

It was accepted and referred to an

AUDITING COMMITTEE,

consisting of Drs. F. B. Parmele, of Rensselaer Co., E. M. Lyon, of Clinton Co., and J. D. Spencer, of Jefferson Co.

DR. CHARLES H. PORTER also read the Librarian's report, and the report of the Merritt H. Cash Prize Essay Fund, which were accepted by the society.

DR. J. O. ROE, of Rochester, read a paper on "Nasal Stenosis," which was illustrated by the demonstration of charts and the exhibition of various instruments. It will appear in a future number of the RECORD.

DR. O. D. POMEROY, of New York, recalled a recent experience of his with regard to closed nostrils, occurring in a gentleman forty-five years of age. He had used a dental engine provided with drills. He also had recourse to a cross-cutting drill. In three sittings he had made a sufficiently large aperture, and the patient was now in a satisfactory condition.

PAPERS READ BY TITLE.

The following papers were read by title, and referred to the Committee on Publication.

"Hystero-Neurosis of the Stomach in Pregnancy," by Dr. John S. Warren, of New York.

"The Forceps," by Dr. J. H. Squire, of Elmira.

"Obituary Notice of Horatio Knight Bellows, M.D., of Norwich," by Dr. Geo. W. Avery, of Norwich.

MEDICAL INDUCTION COILS.

DR. L. E FELTON, of Potsdam, read a paper on medical induction coils, and showed a newly devised cell, for which he claimed advantages over other cells.

DR. ARTHUR MATTHEWSON, of Brooklyn, then made some

BRIEF REMARKS ON TRANSPLANTING LARGE PIECES OF SKIN WITHOUT PEDICLE,

illustrating his subject by the exhibition of photographs taken from a patient. It was a case of transplantation for complete eversion of the left upper lid as the result of contraction from burns. The lid was freed by dissection and transplantation performed of a piece of skin three inches by one and one-half inch without pedicle. The result was union throughout by first intention. The advantages of the operation were said to be the ease of execution, with greater surety of success than by old methods, with pedicle or sliding flaps.

The President announced the

COMMITTEE ON THE PRESIDENT'S ADDRESS,

to consist of the following gentlemen: Drs. Alexander Hutchins, of Brooklyn; H. Jewett, of Canandaigua; and S. G. Walcott, of Utica.

DRESSING OF THE UMBILICAL CORD.

DR. DANIEL LEWIS, of New York, read a paper on the above subject. After briefly considering the accidents and diseases to which the infantile cord was liable, he gave his own method of procedure in taking charge of a case. He referred to the probable fact that trismus neonatorum might be caused by irritation at the umbilicus. Imperfect union of the abdominal walls was a frequent occurrence, as seen from the reports of the New York Hospital for the Ruptured and Crippled. Early abdominal support would lessen the frequency of this accident. From personal experience he would advise that the cord be cut *before* the ligature is applied, and thoroughly emptied of blood and serous contents, thereby reducing the amount of material to be sloughed off to a minimum. It was then tied and twisted sharply three or four times, which torsion so closed the umbilical vessels that hemorrhage was almost impossible, in case the ligature should prove imperfect. A band of rubber adhesive plaster, two by eight inches, was then tightly applied over it and allowed to remain until the parts were thoroughly cicatrized. This device was believed to be sufficient to prevent any protrusion of the navel in predisposition to umbilical hernia.

The following gentlemen were announced as

MEMBERS BY INVITATION:

Drs. J. W. Arnold, of Wayne County; A. P. Ten Eyck, of Rensselaer County; D. M. Lee, of Chenango County; G. L. Ullman, A. T. Van Vrancken, H. R. Stuckweather, and Otto Ritzman, of Albany County.

PERICHONDRITIS AURICULÆ.

DR. THOMAS R. POOLEY, of New York, read a paper on perichondritis auriculæ, and exhibited photographs illustrative of his remarks. This paper will appear in a future number of THE RECORD.

THE SURGICAL TREATMENT OF EPITHELIOMA OF THE CERVIX UTERI.

DR. W. W. POTTER, of Batavia, read a paper on the above subject, in which the various operative measures likely to afford relief or establish a cure in this malignant disease of the cervix were successively discussed. The écraseur was thought to be objectionable. The galvano-cautery and its claims were alluded to, and the objections to its universal application stated. Paquelin's thermo-cautery came next. The advantages of this instrument over others were explained. The last kind of operative procedure considered was the use of the curette, knife, and scissors, supplemented by the potential cautery. One of the four cases recently operated upon by Dr. Potter was narrated in detail.

DR. E. R. SQUIBB, of Brooklyn, remarked, with re-

gard to Dr. Clay's recommendation of Chian turpentine, that this vaunted cancer-specific must now be classed with the utterly useless drugs. Thus, the Middlesex and other hospitals had but recently forbidden its use. The apparently good effect was due to the giving of hope to the hopeless, *i.e.*, the moral effects of enthusiasts upon susceptible, because diseased persons. Probably no real Chian turpentine had ever reached this country; hence, the spurious article was as good as the genuine, for good results had been claimed by American observers also. This was readily explained by what had just been stated concerning the giving of hope to the hopeless.

Dr. Graves assented to the foregoing, allnding to his own experience, which tended to confirm the conviction that Chian turpentine was utterly useless in the treatment of cancer.

A communication from the Medico-Legal Society of New York, was read relative to reform in the Coroner's office. Clark Bell, Esq., would be willing to bring the matter before the society at to-morrow's session.

On motion by Dr. H. G. Piffard, of New York, the communication was received, and the society expressed its willingness to hear the report of Mr. Bell.

The following paper was read by title: "Obituary Notice of Dr. Levi Moore, of Albany," by Dr. J. M. Bigelow, of Albany.

REPORT OF THE COMMITTEE ON LEGISLATION.

Dr. Piffard, of New York, chairman of the committee, submitted their report. It referred to a resolution recommended to the consideration of the State Society, by the Broome County Society, urging the regulation of the dispensing of medical charities, and suggesting that a committee of the State Society ask the Legislature to require all institutions receiving State or municipal aid to restrict the admission of patients, or the dispensing of medicines or treatment, to those only whose pecuniary circumstances evidently demanded assistance. The committee, while it believed that the proposed legislation would prove of great service in controlling the evils connected with the present system in the rural and sparsely settled portions of the State, did not believe that it would be of equal benefit in the larger cities, and were not, therefore, disposed to favor the passage of the general act, as proposed.

The committee also reported that a compilation of the medical laws had been made, and that said laws were printed in the Transactions of 1880.

In answer to an inquiry in relation to the cutting down of bills by town boards, the committee reported that the physician who, on the demand of a properly authorized town officer, renders medical services to the poor, has a claim against the town for services rendered, to be substantiated in the usual way.

The committee also recommended a resolution defining the liability of permanent members to the payment of dues; reported that it had, in accordance with instructions from the society, procured the passage of a medical registration act, and made a report in relation to a proposed drainage act, stating that all necessary powers to that end were now held by the State Board of Health.

On motion by Dr. Wm. C. Wey, of Elmira, it was adopted as the sense of the society.

The society then adjourned to meet at 8 P.M.

First Day—Evening Session.

The society was called to order at 8 P.M., by Dr. Abraham Jacobi, of New York, Vice-President, who introduced Dr. William Hailes, Jr., of Albany. The latter then proceeded to deliver a lecture entitled

A PLEA FOR MORE PRACTICAL WORK IN THE LABORATORIES OF OUR MEDICAL COLLEGES.

After some introductory remarks, Dr. Hailes described various subjects relating to microscopical technology, especially the use of a freezing microtome devised by himself, which possessed certain advantages over other similar apparatus. He secured the interest of his listeners by illustrating his remarks through many excellent images thrown on a screen by means of a stereopticon.

Interspersed between the substance-matter of his lecture were practical hints and suggestions, the value of which was perhaps only apparent to those engaged in similar pursuits with himself. The lecture closed by a brief summary of the history of incubation of the chick up to about the fourth day. All the photographs which served for images upon the screen had been made by himself. They showed very beautifully the embryo chick from the first appearance of the primitive trace, through the various stages of its progressive development, culminating in the clearly-marked differentiation of separate organs. Some of these images, illustrating the origin of the blood-vessels in the area vasculosa, and the rapid establishment of embryonal circulation by the formation of the omphalo-mesenteric vessels, and the sinus terminalis, were especially happy results of diligent research combined and blended with mechanical skill. This exhibit was in all respects a satisfactory one, and the interest manifested by the members was apparent from the crowd of questioners surrounding the doctor after the completion of his lecture.

Wednesday—February 2d.—Second Day—Morning Session.

The society was called to order at 9½ A.M., by the President.

Prayer was offered by the Rev. T. H. Patterson.

The minutes of the preceding day were read and approved.

On motion by Dr. A. Jacobi, a vote of thanks was tendered Dr. Hailes for his interesting and instructive exhibit of the previous night.

The Auditing Committee reported that they had examined the accounts of the Treasurer, and had found them correct in every particular. Accepted.

MEMBERS BY INVITATION.

Dr. S. B. Ward, Chairman of the Committee of Arrangements, proposed the following as members by invitation, and they were duly elected: Drs. M. J. Lewi, T. M. Trego, B. U. Sternberg, and G. H. Newcomb, of Albany; A. Mercer and Frank G. Mosher, of Syracuse; L. A. Van Wagnen, of Madison Co.; Edwin Evans, of Oneida Co.; H. A. Gates, of Delaware Co.; E. C. Seguin, of New York; Henry Ford, of Cazenovia; E. B. Tefft and L. B. Winne, of Albany Co.; J. L. Cooper, of the New Jersey State Society; J. S. Cooley, and F. L. R. Chapin, of Warren Co.; Willis G. Tucker, of Albany; C. C. Chaffee, of Springfield, Mass.; Harris J. Fellows, of Albany; T. L. St. John, of Rensselaer; D. C. Case, of Albany; D. N. Walker, of Herkimer; O. D. Ball, of Albany; W. L. Pierson, of Schenectady; Jas. P. Boyd, Jr., and Jos. Lawe, of Albany.

Dr. Starr, of Rochester, presented a series of resolutions from the Monroe County Medical Society, in relation to changes in the form of printing the pro-

ceedings of the society, which gave rise to a lively and protracted discussion.

On motion of Dr. Wey, as amended by Dr. Hutchison, and further amended by Dr. Piffard, it was resolved, in view of the importance of this matter, to appoint a special committee of three to report on this subject at the next annual session.

Dr. Squibb suggested that, in order to have a fairly representative committee, such committee should be named by the society through its nominating committee. Agreed to.

REPORT OF THE COMMITTEE ON THE PRESIDENT'S INAUGURAL ADDRESS.

Dr. A. Hutchins, of Brooklyn, Chairman of the Committee, reported the following recommendations for adoption:

1. In regard to co-operation with the State Board of Health, a resolution was offered reading:

Resolved, That the county medical societies of the State be requested to instruct their committees on hygiene or public health to put themselves into such relations with the State Board of Health as shall facilitate said board in acquiring such local and general information as it may require.

2. Referring to the interpretation of § 3, Sect. 1, Chap. 746, Laws of 1872, the committee recommend the passage of the following:

Resolved, That the Committee on Legislation be instructed to procure such change in the paragraphs of § 3, Sect 1, Chap. 746, Laws of 1872, as will obviate the legal construction referred to in the address.

3. Relating to such change in the code of ethics of the State Society as shall bring it into harmony with the present conditions of the profession, the following was proposed:

Resolved, That a special committee of five be appointed by the President, to be designated a

SPECIAL COMMITTEE ON THE CODE OF ETHICS,

whose duty it shall be to consider the whole question of desirable changes in the code, and who shall present to the society, at the session of 1882, such suggestions on this subject as their deliberations and investigations may decide.

The various resolutions thus presented were received and accepted.

On motion by Dr. Wey, it was decided that the committee to be appointed in accordance with the last resolution, have the power to fill occurring vacancies.

MISCELLANEOUS BUSINESS.

Dr. A. Jacobi, of New York, presented his report as Censor to the Medical College of Syracuse University. Referred to the Committee on Publication.

Dr Wm. Manlius Smith then read the report of the Delegation to the Pharmaceutical Convention. Received and accepted.

REPORT OF THE COMMITTEE ON ETHICS.

Dr. C. R. Agnew, of New York, read the report of the Committee on Ethics in regard to the charges and counter-charges preferred by Dr. A. L. Carroll and the Richmond County Medical Society on the one side, and Dr. H G. Piffard and the New York County Medical Society on the other, arising out of the admission by the latter society of Drs. Goldman and Black as members. The committee found that the New York County Society and Dr. Piffard were justified in what they had done, and that the charges should be dismissed. Agreed to.

REPORT OF THE COMMITTEE TO CO-OPERATE WITH THE SOCIETY FOR THE PREVENTION OF CRUELTY TO CHILDREN.

Dr. Jacobi presented the report of the committee appointed last year, in accordance with the following resolution:

Resolved, That the President appoint a committee, consisting of five members, to co-operate with the Society for the Prevention of Cruelty to Children, etc.

An elaborate letter from Elbridge T. Gerry, Esq., President of the Society for the Prevention of Cruelty to Children, was embodied in this report. The latter showed the necessity of further legislation in behalf of children employed in factories, also for the better care of children of incompetent or dissolute parents.

On motion by Dr. Squibb, it was resolved that the report be received and the present committee continued, in order to carry out its suggestions and recommendations, the society fully endorsing such recommendations.

REPORT OF THE COMMITTEE ON EXPERIMENTAL MEDICINE.

Dr. John C. Dalton, of New York, presented this report. Bergh's new bill was read, and the fact pointed out that a petition was now circulating to enlist the support of the public for Bergh's proposed measures of repression. The efforts of the anti-vivisectionists were as senseless as they were persistent. Bergh's new bill was identical with his old one. The insincerity of the motives animating these attempts at repression were apparent, and the bottom of the whole movement was nothing but a maudlin sentimentalism. Quotations from Bergh's strictures were then read to illustrate the truth of this assertion, and the necessity for sustained vigilence was set forth.

Dr. Vander Poel stated that active opposition was certainly necessary on the part of members of the Legislature, and they should have the matter properly brought before them.

On motion by Dr. Squibb, the report was received and adopted.

Dr. Chamberlain, of New York, offered the following:

Resolved, That the Secretary of the State Medical Society be instructed to procure the printing and transmission to the Committee of the Senate and Assembly on Public Health, of any matter relative to the Vivisection Bill which may be offered by the committee of this society on Experimental Medicine. Accepted.

Dr. C. A. Post, of New York, offered the following:

Resolved, That it is the unanimous opinion of this society that the bill to prevent vivisection ought not to pass.

Resolved, That the above resolution be signed by the President and Secretary, and forwarded to the Committee of the Legislature on Public Health.

This was unanimously adopted by a rising vote.

MISCELLANEOUS BUSINESS.

Dr. Johnson, of New York, called up the matter of the New York County Medical Society. He moved that the Special Committee on the Code, already authorized, also take into consideration the differences between the Richmond and New York County Medical Societies. Laid on the table.

A resolution from the New York County Society,

that the State Society inquire into the expediency of making a change in the law relative to the divulging of information given to physicians by patients, was dismissed and referred to the Committee on Legislation, with instructions to report thereon in 1882.

Dr. Wey, of Elmira, offered the following resolution, which was accepted :

Resolved, That this society recommend that the county societies empower their several boards of censors to take such measures as may be necessary to carry into effect the Medical Act of May 29, 1880.

Dr. Lewis, of New York, offered the following :

Resolved, That no county society can consider applications for membership from persons who are members of county medical societies not represented in this society.

Carried.

Dr. Squibb's motion, to the effect that 500 copies of Dr. Jacobi's report as president of the committee appointed to confer with the Society for the Prevention of Cruelty to Children be printed for public distribution, was carried.

PAPERS READ BY TITLE.

"Report of the Committee on Hygiene," by E. V. Stoddard, of Rochester.

"A Case of Cerebral Tumor," by J. C. Hutchinson, of Troy.

"Thoughts on Sanitation," by Dr. Harvey Jewett, of Canandaigua.

"A Biographical Notice of Dr. Alfred Bolter, of Ovid," by Dr. J. C. Corson.

CICATRICIAL CONTRACTION OF THE THUMB, AND FINGERS, AND PALM OF THE HAND, RESULTING FROM A BURN.

Dr. A. C. Post, of New York, addressed the society on the above subject, exhibiting a plaster cast of the deformity of the hand alluded to. The report of case will appear in full in a future number of the Record.

Dr. Matthewson thought that the transplantation of large pieces of flexible skin would produce good results in such cases.

Dr. A. Van Derveer, of Albany, had also had good results with somewhat similar procedures.

Dr. J. P. Creveling, of Albany, remarked that in two cases he had seen good results follow the subcutaneous division of cicatricial tissue.

The abstract of a paper on

HYSTERO-NEUROSIS OF THE STOMACH

was read by Dr. J. S. Warren, of New York. From a consideration of several hundred cases he did not believe that there was anything like a specific for this affection, but that each case required a special line of treatment. Vomiting was not always, nor even in most cases, a sympathetic symptom, but arose from certain nerve-influences, or from changes in the thyroid gland, spleen, liver, or kidneys.

Dr. William S. Ely, of Rochester, referred to the diagnostic value of the gastric neuroses in pregnancy. Where a woman has had special cravings in previous pregnancies, which she has experienced at no other time, the recurrence of this craving will often strengthen the suspicion of pregnancy, before evidence is furnished in other ways. In the treatment of vomiting of pregnancy there is one method which will often prove successful, and this is the disregard of regular hours for meals, and urging patients to take small quantities of food often, to go to bed with food under the pillow or near the bed—to steal a march, so to speak, on the stomach, and not wake up its irritability. Discard excessive medication, exclude complications, relieve constipation, and, in moderate cases, the patient's strength can be maintained by the plan named.

Dr. A. C. Post had found an absolutely opposite plan of treatment most successful in such cases. It was his opinion that rectal alimentation would give the best results. Perfect rest and quiet of the stomach was the great desideratum.

A case in point was described, in which food by the stomach was entirely forbidden for three weeks. Absolute abstinence had also succeeded in another case, conjoined with the introduction of the finger into the os uteri.

Drs. W. W. Potter, of Albany, Woodward, of Chemung, R. H. Sabin and Osborne, of Chautauqua, also participated in the discussion.

The President here announced that the Nominating Committee would meet at 5 P.M.

Dr. Van Derveer read a telegram from Clark Bell, Esq., to the effect that that gentleman would address the society on Thursday.

The society then adjourned to meet again at 2.30 P.M.

SECOND DAY—AFTERNOON SESSION.

The society was called to order at 2.30 P.M., by the President.

MEDICINAL ERUPTIONS.

Dr. H. G. Piffard, of New York, read a paper on medicinal eruptions. He stated that, until within a very few years, hardly any drug, except arsenic and the diaphoretics, was credited with a direct action on the skin. Effects upon the healthy skin, following the ingestion of drugs, were rare, yet on this very account important to be recorded for reference. Practitioners should know all the irregular and abnormal effects of remedial agents, lest a medicinal rash be mistaken for an idiopathic affection of the skin, and the unsuspected cause be permitted to remain in operation. Thus far, dermatology had mainly considered the symptomatology and pathology of cutaneous affections springing from what might be termed natural, though frequently obscure causes. There was need of careful observation of a different class of cases : those which arose through the agency of means intended to combat disease, but which in turn might become the originators of morbid action. While in many cases these effects were unusual, and commonly explained as due to some idiosyncrasy, it was none the less important that they should be recognized at the time of their occurrence, and their true cause be ascertained. Owing to the pressure of business, the reading of the paper had to be interrupted before its completion.

Dr. Bulkley said that the subject of the distinction between eruptions produced by drugs, and ordinary diseases of the skin, was one of great practical importance, inasmuch as the practitioner might frequently mistake them and cause needless anxiety.

Although many drugs had been mentioned as occasionally producing lesions of the skin, there were practically but a few which it was necessary to bear constantly in mind ; these were copaiba, quinine, chloral, and salicylic acid or its compounds, named in the order of their importance in this respect.

He afterward added the iodides and bromides, which were omitted as the writer of the paper had not reached them before he was interrupted by the expiration of the time allotted.

The most important medical eruption to bear in mind was that from copaiba, inasmuch as it was so liable to be confounded with the early erythematous eruption of syphilis. Thus, a patient had contracted venereal disease and there might be reason to believe that he had a chancre. He might, at the same time, have a urethral discharge, for which copaiba was prescribed in some mixture. An erythematous eruption appeared, and, if the existence of the possible cause was not understood and borne in mind, it was at once put down as that of syphilis, and the patient was now regarded as syphilitic, with all the prospects which that diagnosis entailed, whereas the sore might have been a chancroid or progenital herpes, and the eruption wholly due to the copaiba. This had frequently happened.

Dr. A. C. Post, of New York, alluded to the liver of the halibut as capable of producing severe cutaneous eruptions. He had himself been subject to a rash of this kind from the same cause.

Dr. Piffard said that there was a case on record of a man having died in consequence of eating stale liver of eels.

Dr. Squibb remarked that the inter connection of the two subjects seemed to him somewhat doubtful. When one considered the enormous quantities of quinine, chloral, and even salicylic acid, which were consumed, and contrasted therewith the limited number of cases of medicinal eruptions reported, the causal relation of the two might be justly doubted.

ADMINISTRATION OF NITRITE OF AMYL.

Dr. Piffard described the way in which this drug should be given in order to circumvent all danger. It consisted essentially of filling a bottle with cotton and then saturating it with the amyl nitrite.

Dr. Squibb remarked that it was quite safe to carry vials filled with the fluid. He was of opinion that the dangers likely to follow a free inhalation of the drug had been considerably exaggerated. If about two-thirds of the contents of a vial had been used, the remainder would be found useless, and should be thrown away.

Dr. E. C. Seguin said: "I can cordially indorse Dr. Piffard's device for giving amyl, as I have used the same plan for some three years. I was led to adopt it because I found that the amyl was often spilled by patients over their shirt-bosoms, or on the carpet of their room after the beginning of the paroxysm for the relief of which they had been smelling the bottle. I might add that I have much less fear of amyl than I had two years ago. It is now my custom to tell patients to sniff hard and rapidly until their faces flush. I have never known any dangerous or unpleasant results to occur. Indeed, one of my female patients once received half an ounce of amyl as an enema by mistake, and the only consequences were universal blushing and an intolerable odor in the house."

INTRA-PARIETAL HERNIA.

Dr. Geo. F. Shrady, of New York, read a paper on the above subject, which was illustrated by the exhibition of a colored drawing. It will appear in the Record.

Dr. Harvey Jewett, of Canandaigua, alluded to the peculiarity of Dr. Shrady's case, and then, in connection with the general subject of hernia, narrated the following:

"In my earlier practice, before the use of chloroform, I was called to operate for strangulated femoral hernia. The patient had hiccough, stercoraceous vomiting, and all the indications of speedy dissolution. I declined to operate, as the case would soon terminate by death. At the solicitation of the friends of the patient I performed the operation and left the patient to die. After forty-eight hours, feculent matter, together with a large lumbricoid worm, appeared at the place of operation. The contents of the bowels were discharged at the place of the wound for about six months, during which time, with the aid of injections, the external discharge gradually diminished, and at length entirely ceased. The contents of the bowels passed by the natural channel, and the patient enjoyed uninterrupted health for thirty years."

Dr. Post thought the case might be considered an unusual one of conjoined ventral and inguinal hernia. A remarkable case of traumatic ventral hernia occurring in the New York Hospital was also described.

Dr. Van Derveer dwelt on the exceptional nature of Dr. Shrady's case, and did not remember a similar one.

Dr. Mercer, of Syracuse, related a case in which a large mass of intestines had protruded from an abdominal wound received in a quarrel. The protruding intestine was caught between the muscular layers of the abdominal parietes, and there became strangulated.

Dr. E. R. Squibb exhibited a series of micro-photographs illustrating the histology of pseudo-polypus of the colon, as described by J. J. Woodward, Surgeon, U.S.A., in the *American Journal of the Medical Sciences* for January, 1881.

Dr. H. Knapp, of New York, read a paper on

EXOSTOSIS OF THE FRONTAL SINUSES.

After developing the importance of the subject and dwelling on the rarity of bony growths of the frontal sinuses, Dr. Knapp gave a comprehensive *résumé* of known cases. He then proceeded to the detailed description of his own cases. It appeared that only in two instances were the operative measures attended with success. One of these belonged to Dolbeau, of Paris, and the second was the last of his own cases.

Dr. A. C. Post, of New York, narrated a case of osteo-sarcoma, in which the dura mater had to be exposed by an operation. The patient afterward recovered from the effects of this surgical procedure.

PAPERS BY TITLE.

"Obituary Notice of Dr. Alfred Boller, of Ovid."

"Thoughts on Sanitation," by Dr. Harvey Jewett, of Canandaigua.

REPORT OF THE COMMITTEE ON HYGIENE.

Dr. E. V. Stoddard, Chairman of the Committee on Hygiene, called the attention of the society to the work that had been done by the committee. He stated that, on consultation with the State Board of Health as to the subject to be considered, it had been decided that attention should be directed to the subject of the prevention of contagious diseases in schools, especially of diphtheria. With this view the committee had thought it best to invite special attention to this matter, and had asked members of the profession to do all in their power to discover the relative influence on the contagiousness of diphtheria: first, from direct personal contact; second, from clothing worn by the sick; and, third, from unsanitary surroundings. Observations on these points had been called for, and over three hundred responses from physicians had been received. The

general testimony was unanimous in favor of the great contagiousness of the disease. The committee proposed to suggest that their successors prescribe the gathering of some rules of study and observation in the matter, and that sanitary measures be taken looking to the isolation and suppression of all cases of the disease from families, and from attendance at school; and further, the supervision of the public schools by a sanitary inspector. This question of *quarantine* in the public schools as well as the family was urged by the committee, and will serve as the subject of the coming year.

Dr. Elisha Harris, one of the State Commissioners of Health and Secretary of the State Board, invited the attention of the society to the present widespread prevalence of diphtheria. The utility of the general observations and records of the medical profession relating to the causation and prevention of this malady was obvious, and while we all gave attention to this subject, Dr. Harris urged that the unguarded causes of the distribution of diphtheria should be brought under such sanitary control as might be possible. He explained the special importance of regulating the domestic quarantine, or isolation of all who were convalescing, as well as those who were yet in the sick-room or at the height of the disease. The evidence upon this matter showed conclusively that many a convalescent, when allowed to go to school or otherwise to rejoin the community, had conveyed the infection of diphtheria.

The State Board of Health found it a duty to investigate the course of this disease as respects the factors that entered into its modes of distribution, its infectious as well as other causes. Though not unusually malignant at present, it was so prevalent, and the total mortality from it so great, that the physicians of this State could do great service by teaching and inducing the necessary care in preventing the spread of the infection that pertained to this destructive malady.

The opportunities that had from time to time been afforded us for investigating the course and causes of diphtheria in sparsely populated districts, and during the past autumn in a wilderness where it had not before been seen, gave results which showed how important it was to regulate the whole matter of domestic and personal isolation of the sick, even until convalescence had ended in health.

In connection with these remarks, the doctor called attention to the following table:

From health officers of villages, in December, 1880: diphtheria, 29; malaria, 40; typhoid fever, 29; measles, 16; mumps, 0; scarlet fever, 25; small-pox, 7; whooping-cough, 19.

From physicians in towns and incorporated villages, in January, 1881: diphtheria, 50; malaria, 20; typhoid fever, 18; measles, 45; mumps, 6; scarlet fever, 48; small-pox, 4; whooping-cough, 12.

VESICAL CALCULI, WITH OPERATIONS.

Dr. A. Van Derveer, of Albany, read a paper on the above subject, which will appear in a subsequent number of the Record.

DOUBLE TALIPES EQUINO-VARUS.

Dr. A. M. Phelps, of Chateaugay, read a paper containing the description of an extreme case of this kind occurring in a little girl six and a half years old. The paper was illustrated by the demonstration of a model and the exhibition of photographs. After tenotomy, the feet relapsed to nearly the old position. The doctor made a free incision through the inner side and sole of the foot, dividing the contracted parts in their respective order. The feet were then brought into position and put up on a modification of Neil's board; the wounds gaped an inch and a half. The patient then went on crutches, swinging both feet. The wounds healed after four months. An ordinary shoe, with a stiff counter, was now worn on the left foot, and a Sayre's shoe on the right; the patient could walk, however, without any shoe.

Dr. A. C. Post, of New York, said that in many cases of club-foot subcutaneous division of the constricted tissue was inadequate, sometimes even dangerous. Free open division, under antiseptic precautions, was often a better procedure.

At the instigation of Dr. Jacobi, Dr. Post then related his case of torticollis, in which an open operation had produced highly satisfactory results.

Dr. J. C. Hutchison, of Brooklyn, thought that the results of Dr. Phelps' case were certainly encouraging. He would be tempted to proceed in a similar manner in a case of that kind.

ON THE EARLY DIAGNOSIS OF SOME ORGANIC DISEASES OF THE NERVOUS SYSTEM.

Dr. E. C. Seguin read a paper on the above subject, which will appear in a future number of The Record.

The society then adjourned to meet in the Assembly Chamber of the new capitol, at 8 o'clock, to listen to the annual address of its President.

Second Day—Evening Session.

THE PRESIDENT'S ANNUAL ADDRESS.

The society convened in the Assembly Chamber of the new capitol, at 8 P.M., when the Vice-President, Dr. A. Jacobi, introduced Dr. William H. Bailey, who delivered the annual address. He spoke mainly on the "duties and opportunities which fall to our profession in its relations with our fellow-men."

The progressive perfection of medical sciences was set forth. The medical student of to-day, with his greater facilities for acquiring knowledge, was contrasted with the student of former times. The corresponding increase of responsibility was dwelt upon.

"The students of law and divinity are required to pass through a prescribed course of mental training and study. The catalogues of institutions for such instruction show a large majority of their students to have been college graduates. But the catalogues of our medical schools, I am sorry to say, show only a small proportion of such. And yet who believes that the medical student requires less preparation and mental training than they? Is it not true that no standard of instruction can be too high for the education of men, from whom so much is expected and required, in preparing them for a work calling for such nice powers of observation, of discrimination, and of inference?"

Medical societies were likened to the guilds of the olden time, and the various advantages of such fraternization were pointed out. It was thought that the profession might drop its written law of ethics without detriment or danger. "Our profession has gradually advanced in its value and efficiency, constantly increasing its sphere of usefulness and influence, greatly benefiting and improving the moral, social, and physical conditions of the human race. I think it is, moreover, safe to assert that, with the rapid progress making in medical science, the future contains greater and still more honorable possibilities for the intelligent and competent practitioner."

The President closed his address in the following words: "This, then, is the urgency of my appeal to you, this my entreaty and hope, that with the cultivation of the kindest feelings toward each other, friendly counsel and interchange of experiences, symphathetic words and encouragement, we may emulate each other's virtues, condone the faults which inhere in our poor human nature, and thus, having faithfully sought to discharge our whole duty in life, winning the esteem of our fellow-men, we may also merit and receive the approbation of Him, the greatest Physician, whose verdict of 'Well done, thou good and faithful servant,' is the highest praise that can reward our honorable stewardship."

The address was listened to with marked attention. At its close a vote of thanks was tendered to the President.

The society then adjourned to the Delavan, and partook of the annual banquet. About 135 persons were present. Rev. C. W. Camp, of Kingston, said grace. The "feast of reason and the flow of soul" were inaugurated by appropriate remarks from the retiring President, Dr. Wm. H. Bailey. The following were some of the toasts:

"The State Society: now in the vigor of manhood, it has had its days of childhood." Responded to by Dr. S. O. Vander Poel.

"The Ex-Presidents: once in the chair, now on the floor." Responded to by Dr. Joseph C. Hutchison.

"The clergy: always called upon to finish our work, and charge our blunders to Providence." Responded to by Rev. W. W. Battershall.

"The press: we know its power; may it rise to be the instructor of the people." Responded to by Mr. Wm. H. Bogart.

"The legal profession: they worry lots of fellows into becoming our patients." Responded to by St. Clair McKelway.

"The Board of Regents: higher education for the medical profession." Responded to by David Murray, LL.D.

"The State Board of Health: we are in hearty sympathy with its work." Responded to by Hon. Erastus Brooks.

Third Day—Final Session.

The society was called to order at 9 A.M. by the President.

Prayer was offered by the Rev. W. D. Nicholas.

The minutes of the previous day were read and approved.

Miscellaneous Business.

A communication was received from the Westchester County Medical Society, and referred to the Committee on Legislation.

Dr. W. M. Smith, of Manlius, read the report of the Committee on Publication. It was received and accepted.

Dr. H. G. Piffard offered the following on behalf of the Committee on Legislation:

Resolved, That all the paragraphs contained in the Appendix to By-Laws (see Trans. of Med. Soc. State of New York for 1880, p. 23), beginning with Art. II., Sec. 6, be repealed, except those paragraphs reading:

"Three censors shall annually be elected from each censorial district, all of whom shall be residents of the same county; and,

"The first and second senatorial districts, as established by law in 1836, shall be called the *Southern;* the third and fourth the *Eastern;* the fifth and sixth the *Middle;* and the seventh and eighth the *Western Censorial District.*"

The Abolition of the Coroner's Office.

Mr. Clark Bell, of New York, then read an exhaustive address on the above subject, in which he advocated the abolition of the Coroner's office, and the appointment of competent medical men to take charge of all such investigations. He urged that the framing of a new law be recommended to the Legislature, and suggested the recent Massachusetts law as a model.

Dr. Govan, of Stony Point, said that he had been Coroner in his county for many years, and he had often done away with a coroner's jury. He had received information from reliable sources that this was a legal action on his part.

Dr. Potter moved to refer the whole matter to the Committee on Legislation, with instructions to report at the next annual meeting.

Dr. Mosher thought such delay was not desirable.

Dr. Squibb was willing to let the matter lay over one year for better consideration.

Mr. Bell expressed an opinion that delay was not advisable.

Dr. Squibb moved an amendment that the paper be referred to the Committee on Publication, and also to the Committee on Legislation, with instructions to confer with the representatives of the Medico-Legal Society at their earliest convenience.

Carried.

The following

Special Committee on Ethical Revision

was announced: Wm. C. Wey, of Elmira; C. R. Agnew, of New York; S. O. Vander Poel, of Albany; Wm. S. Ely, of Rochester; Henry G. Piffard, of New York.

The following were adopted as

New By-Laws.

Permanent members of ten years' standing, who have paid up all their dues, and permanent members of the age of sixty years and upwards, who have been permanent members for ten years, on making application to the Secretary, accompanied with the Treasurer's certificate that all dues have been paid up to date, shall be placed on the list of Retired Permanent Members, and shall thereafter be exempt from payment of dues, and have the rights and privileges of honorary members. Such retired permanent members may be restored to full permanent membership on payment of half the amount of dues that would have accrued during their period of retirement, if they had not been retired.

Carried.

The following were proposed and elected

Members by Invitation:

Drs. Lewis Balch and L. B. Hoit, of Albany Co., C. C. Schuyler, of Rensselaer Co.

Enforcement of the Act to Regulate the Licensing of Physicians.

The following resolution was read by Dr. Smith, of Manlius:

Resolved, That the Medical Society of the State of New York advises the various county medical societies that form its constituency, to endeavor to secure the co-operation of the other incorporated county and district medical societies throughout the State in the enforcement of the "Act to regulate the licensing

of physicians and surgeons," passed May 29, 1880. Carried.

PAPERS READ BY TITLE:

"Biographical Sketch of Dr. Edward R. Hun," of Albany, by Dr. Samuel B. Ward, of Albany.

"Obituary Notice of Dr. Charles A. Robertson," of Albany, by Dr. J. S. Mosher, of Albany.

"A Case of Cystic Degeneration of the Chorion," by Dr. James Chapman, of Medina.

"Summary of Cases of Accouchement from January 8, 1819, to May 1, 1879," by Dr. J. B. Cowles, of Dunham.

A paper was read by DR. C. L. STILES, of Owego, entitled

A DEVICE FOR RETAINING DISLOCATIONS OF THE CLAVICLE AT ITS DISTAL END.

It will appear in a future number of the RECORD.

DR. GEORGE H. FOX read a paper on

THE BENIGN ASPECT OF SYPHILIS,

which gave rise to a protracted discussion as to whether the disease was eradicable or not, and benign or malignant.

Drs. Bulkley, Pooley, Ferguson, of Troy, Ward, Van Derveer, Piffard, Squibb, and Curtis, participated. The weight of opinion was decidedly in favor of regarding syphilis as a disease which had stronger tendencies toward malignancy than benignity. It was, however, admitted by all that occasionally cases did occur which, from the lack of all grave manifestations, deserved the epithet benign. On the other hand, it was pointed out that the choice of the expression was an unfortunate one, on account of its leading one to form wrong conclusions. Benign suggested too much of harmlessness, innocence, and innocuousness, to make its association with such a disease as syphilis seem either quite just or entirely desirable.

The following paper was here read by title, and referred to the Committee on Publication:

"The New York State Inebriate Asylum: A Defence of its Management." By Dr. George Burr, of Binghamton.

APPROPRIATIONS FOR THE SECRETARY AND TREASURER.

DR. SQUIBB offered the following:

Resolved, That the increasing labors of the Secretary and Treasurer of the society be recognized and acknowledged by adding $100 to the already appropriated annual compensation of the Secretary, and $50 to that of the Treasurer. Carried.

REPORT OF THE COMMITTEE ON LEGISLATION.

The committee recommended the following, through the Chairman, Dr. H. G. Piffard:

Resolved, That, in the opinion of this society, it is desirable for the Legislature to thoroughly amend and revise the laws of this State in regard to the office and duties of coroners, and would recommend for their consideration the recent statute act adopted by the State of Massachusetts.

The following was also recommended:

Resolved, That the thanks of this society are due to the Medico-Legal Society of New York, and to Clark Bell, Esq., for the action they have taken in reference to the matter of Coroner's law.

Both resolutions were unanimously accepted.

REVIEW OF THE SECOND TRIAL OF JESSE BILLINGS FOR MURDER.

This was the title of a lengthy paper by Dr. Lewis Balch, of Albany. He gave a detailed account of the entire subject, and explained the tests made of the effects of shots into the human skull, exhibiting a number of skulls of the subjects used in his experiments, as well as that of the murdered woman. A full description of the various fractures was also given. Referred to the Committee on Publication.

The Committee on Legislation reported by title the Act of 1841 referring to the censors of the Albany Medical College, and recommended that the act be published in full in the Transactions of 1881.

REPORT OF THE COMMITTEE ON NOMINATIONS.

The Committee on Nominations presented the following report:

President.—Abraham Jacobi, of New York.

Vice-President.—William Govan, of Stony Point.

Secretary.—Dr. Wm. Manlius Smith, of Manlius.

Treasurer.—Dr. Chas. H. Porter, of Albany.

Censors.—Same as last year.

Committee of Arrangements.—Dr. S. B. Ward, F. C. Curtis, J. S. Mosher, all of Albany.

Committee on By-Laws.—Wm. C. Wey, of Elmira; Alex. Hutchins, of Brooklyn; C. E. Witbeck, of Cohoes.

Committee on Hygiene.—Drs. E. V. Stoddard, of Rochester; Stephen Smith, of New York; Jacob S. Mosher, of Albany; J. Foster Jenkins, of Yonkers; Caleb Green, of Homer; E. Hutchinson, of Utica; Harvey Jewett, of Canandaigua.

Committee on Legislation.—Albert Van Derveer, of Albany; Alex. Hutchins, of Brooklyn; H. G. Piffard, of New York.

Committee on Medical Ethics.—Drs. C. R. Agnew, of New York; S. O. Vander Poel, of Albany; E. M. Moore, of Rochester.

Committee on Prize Essays.—Drs. T. F. Rochester, of Buffalo; J. P. White, of Buffalo; W. S. Ely, of Rochester.

Committee on Publication.—Wm. Manlius Smith, of Manlius; H. D. Didama, of Syracuse; C. H. Porter, of Albany; J. Foster Jenkins, of Yonkers.

Censor of College of Medicine, Syracuse University.—W. S. Ely, of Rochester.

For Permanent Members.—First District: John C. Peters, F. A. Castle, T. R. Pooley, J. C. Dalton, of New York County; W. H. Dudley, of Kings County. Second District: N. H. Freeland, of Westchester County; Smith Ely, of Orange County. Third District: C. E. Nichols, of Rensselaer County; C. E. Whitbeck, of Albany County. Fourth District: Henry Gray, of Washington County; E. F. Edgerly, of Essex County. Fifth District: C. C. P. Clark, of Oswego County. Sixth District: W. W. Crandall, of Alleghany County; S. H. Peck, of Tompkins County. Seventh District: Peter M. Wise, of Seneca County. Eighth District: Wm. Chace, of Chautauqua County; Henry Lapp, of Erie County.

For Honorary Members.—J. C. Bucknell and William Farr, of London, England.

Eligible to Honorary Membership.—J. Lockhart Robertson, Sidney Ringer, of London, England; T. S. Clouston, of Edinburgh, Scotland; Roberts Bartholow, of Philadelphia.

Delegates to State Medical Societies.—New Jersey: Drs. H. G. Piffard, of New York; W. Govan, of Stony Point. Massachusetts: S. G. Wolcott, of Utica; J. C. Hutchison, of Brooklyn; J. V. Kendall, of Baldwinsville. Michigan: C. F. Bacon, of Fulton. Vermont: E. M. Lyon, of Plattsburg; R. W. Taylor, of New York. Pennsylvania: T. H. Squire, of Elmira.

Delegates to International Medical Congress, London.—Drs. T. F. Cock, of New York; Jos. C. Hutchison,

of Brooklyn. Alternates: Drs. C. R. Agnew, of New York; N. C. Husted, of Tarrytown, N. Y.

Delegates to Canadian Medical Association.—B. F. Sherman, of Ogdensburg; J. B. Andrews, of Buffalo.

Delegates to American Medical Association.—Drs. A. C. Post, L. D. Bulkley, and G. H. Fox, of New York; J. V. Kendall, of Baldwinsville; H. R. Ainsworth, of Addison; C. G. Bacon, of Fulton; G. W. Cooke, of Otego; F. R. Sturgis, of New York; A. Coe, of Oswego; J. R. Boulware, of Albany; Conant Sawyer, of Ausable Forks; W. U. Coit, of Champlain; J. B. Graves, of Corning; F. L. R. Chapin, Glen's Falls.

Special Committee on Publication of Transactions.—J. C. Dalton, of New York; W. H. Bailey, of Albany; Thos. F. Rochester, of Buffalo.

The President and Secretary received authority to fill all vacancies.

All the nominees were duly elected officers of the society for the ensuing year by an affirmative ballot cast by the Secretary.

On motion by Dr. Cook, of Otego, a vote of thanks was tendered the retiring President for the faithful, impartial, and efficient discharge of his duties.

After the retired President had returned his thanks in appropriate words, the society adjourned to meet in the city of Albany, on the first Tuesday in February, 1882.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 30, 1881, to February 5, 1881.

Vollum, E. P., Major and Surgeon. Granted leave of absence for six months on surgeon's certificate of disability, with permission to go beyond sea. S. O. 24, A. G. O., January 31, 1881.

Burton, H. G., First Lieut. and Asst. Surgeon. Assigned to temporary duty at Ft. Niagara, N. Y. S. O. 18, Dept. of the East, February 1, 1881.

Daily Edition of "Medical Annals," Albany, New York.—During the recent session of the State Society, the *Medical Annals*, of Albany, published two daily editions containing excellent reports of the proceedings of the meeting of the previous days. Too much credit cannot be given to the Editing Committee for their enterprise in the matter.

International Congress for the Abolition of State Regulation of Prostitution.—At a meeting of this Congress in Genoa recently, the following resolutions were adopted: 1, everything relating to prostitution must be made subject to the Common Law of each country; 2, all legal guarantees of personal liberty must be equal for the two sexes; 3, the law must not provide or tolerate any official registration of prostitutes, or any official recognition of prostitution as the status of a social class; 4, the law must not sanction or tolerate any violation of the rights possessed by every woman over her own person; 5, the law must not allow imprisonment, except upon a judicial sentence passed in open court, upon evidence on oath or affirmation of a legally defined offence, and after full opportunity of defence for the accused; 6, all policemen, when performing executive duties, must be in uniform; 7, all officers of the law must be fully responsible for all their acts before the ordinary courts.

And the Congress rejects every regulation of prostitution, whether established by the State, by the Commune, or by any other authority.

The University Hospital, at Philadelphia, has been given the sum of $50,000 with which to erect a new wing for incurables in connection with the hospital. Efforts are being made to raise an endowment fund of $500,000 for the hospital.

The Anesthetic Mixture commonly used in the Vienna General Hospital is composed of alcohol, 90 parts; ether, 90 parts; chloroform, 300 parts. Billroth has used this for nine years without a death, except one that occurred last summer.

The Etiology of Cancer.—Mr. Herbert Snow (*Lancet*) comes to the following conclusions as the result of a study of a large number of cases of cancer:

1. Hereditary tendency, as a predisposing cause of cancer (at all events, of mammary and uterine cancer), is almost valueless, if not entirely so, and in practical diagnosis should be altogether ignored, as misleading.

2. Mechanical injuries directly produce cancer in a certain percentage of cases; but this percentage is small.

3. As direct and immediate causes of cancer (especially of uterine cancer), mental trouble and hard work are very potent agents, and exert more influence than any other antecedent within our present knowledge.

The New York Academy of Medicine.—At the stated meeting held on the evening of the 3d inst., President Fordyce Barker, M.D., LL.D., delivered his second inaugural address, which was replete with valuable suggestions, and was listened to with marked attention. The occasion was made one of mutual congratulation over the prosperity of this medical organization. Brief addresses were also made by ex-Presidents Dr. Willard Parker, Dr. Austin Flint, and Dr. S. S. Purple, and invited guests, Dr. Beverly Cole, of San Francisco, and Dr. John P. Gray, of Utica, after which all were invited to partake of "the loving cup" and a bountiful collation. A full report of the meeting will be given hereafter.

A Nurses' Training-School in Brooklyn.—A training school for nurses, modelled after the New York Training-School, has been established in Brooklyn, in connection with the Brooklyn City Hospital.

Local Application to Diphtheria.—Dr. C. C. P. Clark, of Oswego, N. Y., speaks very highly of the value of the application to the fauces twice daily of the liquor ferri persulphatis in cases of diphtheria. He says: "It is certainly worth all the other remedies I have ever tried, many times over."

Original Communications.

NERVOUS DISEASES CONNECTED WITH THE MALE GENITAL FUNCTION.

By GEORGE M. BEARD, A.M., M.D.,
NEW YORK.

(Continued from page 509, No. 496, May 8, 1880.)

REFLEX IRRITATION AS A CAUSE OF NEURASTHENIA—CLINICAL VARIETIES OF NEURASTHENIA—SEXUAL NEURASTHENIA, AS REFLECTED FROM STRICTURES AND PHIMOSES AND THE PROSTATIC URETHRA—RESULTS OF OPERATIONS—SEXUAL NEURASTHENIA IN WOMEN—UNDER-ESTIMATE AND OVER ESTIMATE OF SYMPTOMS.

VI.

THE body is a bundle of reflex actions. An irritation in any one part is liable to produce an irritation in some other part, the nature and locality of which will depend on the degree of irritation and the constitution of the individual.

This is true of all parts of the body, on the surface and beneath the surface, and of all organs, including, probably, the brain and spinal cord, injuries to which may be transmitted to other portions of the body, or to other portions of their own substance, indirectly as well as directly.

There are certain organs, however, which, on account of abundance and complexity of their own supply, and the indispensability of their functions to life and the perpetuation of life, are pre-eminently centres or foci of reflex irritation. Among the most conspicuous of these reflex centres are: the stomach, the digestive apparatus, including the liver and intestines, the prostatic urethra, the uterus, the ovaries, and the eyes.

Some of the clinical varieties of neurasthenia derive their names from the fact that one organ or set of organs are more particularly involved in some cases than in others, and, either as causes or effects, are the chief avenues of suffering, and require special treatment and hygiene.

Thus, we have cerebral neurasthenia, spinal neurasthenia, digestive neurasthenia, sexual neurasthenia. All these and other varieties not necessary to mention here, are simply special and varying manifestations of a general neurasthenic state; to be diagnosticated and treated, however, with reference to location, constitution, and the special needs of each individual. Theoretically and practically, it is necessary to make these distinctions in our study of the cases, although we may not use or even think of the terminology here employed.

Of these clinical varieties the sexual is, on the whole, the most frequent, after the cerebral; and many of the cerebral and spinal forms, and even the digestive varieties also, take their origin in, or are made worse by the irritation of the reproductive system.

Neurasthenic symptoms, including many or all previously described here or elsewhere, may be excited, kept up, and aggravated by the following conditions of the genital system in the male.

Phimosis or redundant prepuce; stricture; irritable and congested prostate. Next to the stomach, the prostatic urethra is probably the most important centre of reflex irritation of the body. There is every reason, physiological and anatomical, why it should be so, and a close study of the symptoms of nervous debility proves that it is so. A morbid state of this part of the body is both an effect and a cause of nervous exhaustion; for on the one hand it is impossible for one to have an irritable prostate, and yet be in good health in other respects; and on the other hand it is impossible for one to suffer from nervous exhaustion for a long time and not suffer in the prostate urethra. The symptoms of irritation of the prostatic urethra are:

First.—True spermatorrhœa; that is, a flowing away of spermatozoa and spermatic globules in the urine and at stool.

Second.—Frequent urination night or day, or both. This may or may not be accompanied by excess in the secretion of urine.

Third.—Pain and exhaustion after defecation or urination.

Fourth.—Excessive sensibility of the urethra in the prostatic region, or in the entire length; urethral spasm and erectile excitability.

Fifth.—Redness and swelling of the lips of the meatus.

Sixth.—Sweating of the scrotum.

Seventh.—Pain in the testes.

Eighth.—Pain, heaviness, burning sensation in the perineum, sometimes neuralgic in character, during coitus, with numbness.

Ninth.—Varicocele and relaxed scrotum.

Tenth.—Flaccidity, coldness, or gristle-like appearance of the penis, with greater or less degree of impotence, in various and familiar manifestations.

Eleventh.—Coldness of the penis and scrotum, persistent or varying.

Twelfth.—Prostatorrhœa; a flowing of the prostatic fluid (without spermatorrhœa) after stools, or in the urine, or after erection or sexual excitation; weeping penis.

These local symptoms may be accompanied with any one of a very large variety of neurasthenic symptoms in other parts of the body, as the brain, the spine, and the stomach; but the diagnosis of sexual neurasthenia is only defined when there is some one, or, as is usually the case, a number of the above local symptoms.

In regard to reflex irritation from phimosis and contracted meatus and stricture, there are two prevailing errors; one is, that when any of these conditions are found in a case of neurasthenia, they are the sole or chief cause of that neurasthenia, and that the removal of these causes by surgery will be sure to cure.

The other error is, that these conditions have nothing to do with neurasthenia, and that local treatment for their removal is never needed. Experience and close study of these cases—watching them for years—shows us that between these two extremes lies a valuable truth.

Phimosis, redundant prepuce with smegma, contracted meatus, and stricture, may, and do, in some individuals, excite and originate neurasthenic symptoms, and the removal by surgery of these conditions is an aid, sometimes an indispensable aid, to successful treatment; but constitutional as well as local treatment is required, and the co-operation of time and hygiene also, in order to bring about the best results. These conditions may even cause insanity.

When the nervous system becomes depleted of its nervous force, then this local irritation from stricture, phimosis, or redundant or adherent prepuce, may become the excitant or aggravant of nervous symp-

toms. It always takes two factors to make any disease: the subjective must be united with the objective—what comes from without must be united with what comes from within, before they can be combined in any morbid condition of the system.

The surgical world is divided between the traumatic and the constitutional form of hip-diseases. Some have attributed these diseases to constitutional injury, and others to traumatic. One might as well ask whether the acid or the alkali were most important in making soda-water; it is the union of the two that produces the result; either alone being powerless. To advocate exclusively either the constitutional or the local origin of diseases of this kind is non-expertness—looking at half the truth instead of the whole truth. It is local injury acting on constitutional tendency that produces hip-diseases, that produces cancer, that produces consumption; neither influence alone being competent to produce the effect any more than alkali or acid alone can make soda-water.

When a storm sweeps through the forest, it fells only those trees that are prepared to fall; when irritations radiate from any nerve-centre, they excite nervous symptoms only when the system has been prepared for it by debilitating conditions.

There are no greater disappointments in medicine and surgery than for those who have operated for phimosis, stricture, or contracted meatus, with the expectation that immediately after the operation the patient will get well of all his neurasthenic symptoms.

The disappointments that have attended these operations have come partly from expecting altogether too much. Surgeons expect the paralyzed child to get up and walk next day after this operation has been performed; they expect epileptic fits will cease; they expect that insanity will be cured right on the spot.

Now, it is true that in some cases, especially in children, we do get just these quick and startling results in a certain proportion of instances, but we do not find them in the class of nerve-patients to which my paper is devoted. In these cases the symptoms have been a long time coming on; they have advanced not boldly as a lion, but as a thief in the night; and they will disappear not rapidly, but slowly, perhaps almost imperceptibly, the operation being the removal of an impediment to their treatment.

Some of these cases would have been nervous, even had they not been affected with stricture or phimosis, although their nervous symptoms may have been made worse, and kept up in part through the irritation of a stricture or phimosis or smegma, with redundant prepuce. Operating in such cases is like taking away an obstruction in the road in the way of a carriage; the load has still to be drawn after the obstruction is removed, and force is required to draw it, but far less than was needed prior to the removal of the obstruction.

It is not well to depend exclusively upon the operation for the cure of the symptoms that are connected with phimosis. Accessory and supplementary treatment of various kinds is needed after the operation is performed.

This operation, in these cases, is, indeed, but one of many useful therapeutic measures, and adjunct to medical and hygienic treatment; it removes an obstacle to the progress of the cure, and allows the medicines employed to have freer course. I would no more depend on the operation alone, for cure of these cases, than I would depend on the cure of asthenopia, or any disorder of the eye, for the entire relief of the neurasthenic symptoms with which these disorders of the eye are so often associated. Trimming one branch of a tree does not trim the whole tree. Myopic and astigmatic eyes are, very often, the centres of reflex irritation to the whole body, and of such importance in the pathology that the general neurasthenia cannot be cured without treating the eye; but to depend on the treatment of the eye for the cure of the neurasthenia is unphilosophical, and is, very often, the cause of disappointment to the patient, in cases of this kind. Dr. Roosa's reasoning on this question is in harmony with the facts.

In regard to the nature of this accessory and supplementary treatment, I may say that it has been that which is used for general neurasthenia, as described in my work on that subject. There is no specific for this state; there is no one prescription that can cure it. We must do not one thing, but many things, studying each case as to its individuality, if we would get the best attainable results. In a number of these cases I have used the treatment for neurasthenia for some time before the operation was performed, and have secured good results thereby, but only up to a certain point. After the operation the medical treatment was more successful.

One effect of phimosis, as also of redundant prepuce without actual phimosis, is arrested development of the penis. The pressure of the skin upon the glands undoubtedly interferes with circulation and nutrition, and hence it is that we so often find these parts to be so very small in persons where there has been from infancy this phimotic condition. One effect of operative procedure is to allow the parts to grow, by removing the mechanical pressure. Dr. M. Josiah Roberts tells me that he has known a case where simply stretching the prepuce so far removed the pressure that the organ grew to such an extent as to protrude beneath the skin, so that phimosis no longer existed. Effects of this kind are of course more probable in the young than in adults.

On the other hand, there may be a good degree of phimosis, and the prepuce may be both redundant and adherent from birth, and there may be quite a close stricture without exciting any nervous symptoms that can be traced to these conditions. It is quite safe to assert that in at least one-half of the healthy adults there is either phimosis or redundancy of the prepuce, with or without adherence. Here comes the question, What is a normal penis?

In order to settle this problem, I requested the proprietor of one of the Russian bath establishments of this city to investigate the matter among his patrons during the past year. He tells me that more than one-half of the bathers have either phimosis or redundant prepuce sufficient to about cover the gland. I have studied this question at one of these baths, at times when large numbers were bathing, and my observations agree with those of the proprietor.

Out of eighty cases of general and sexual neurasthenia in adult males that have been under my care, and of which I have preserved statistics of the condition of the prepuce, I find that in thirty-six cases, over one-third, there was phimosis or redundancy, with or without adherence.

I have had treated twelve cases of sexual neurasthenia by circumcision, or by stretching. The operations have been performed by Dr. Francis D. Buck and Dr. M. Josiah Roberts. In one case an immense quantity of *hardened smegma*—the accumulation of

years—was removed. Some of these cases are very remarkable indeed, as illustrating on the one hand the complexity and variety of symptoms from which neurasthenics suffer; and, secondly, as illustrating the effects that are obtained by the combination of medical and surgical treatment, patiently carried out and varied from time to time, according to the needs of each case. In none of these cases did any striking or brilliant result follow at once after the operation, but all have since been improving.

Case XXIX.—In this case—that of a gentleman over thirty years of age—there was congenital phimosis to such an extent that it was possible to urinate only in a very small stream. Any number of neurasthenic symptoms accompanied this state; among them, unusual flushing of the face from very slight cause, or no cause at all, exhaustion, lumbar pain, etc. The relief following the operation was very great, but it was not even moderately satisfactory until medical treatment of various kinds had been used. This patient was very susceptible to remedies, and required to be treated very cautiously and carefully. He has now improved, and is in good working condition. The operation did not cure him, but it removed the obstacle in the way of relief.

Case XXX.—This was a very remarkable case in every respect. The amount of redundancy of the prepuce was not very great, and there was not much phimosis, but it was sufficient to justify an operation. The neurasthenic symptoms accompanying the condition were, attacks of profound mental depression, urging on to suicide; lumbar pain, fear of society, anthrôpophobia, very rapid pulse, salivation, sweating hands, very extraordinary urethral hyperæsthesia, as well as irritable prostate. There were a number of interesting facts connected with this case. One was, he had been very fond of smoking, and had indulged in the habit until he became neurasthenic, when he was compelled to give it up. His fear of society was so great that on going into company he would break out into profuse perspiration, so that even his underclothing would be saturated. He suffered also from excessive urination. He was also a sufferer from congestion of the eyes. One interesting fact in connection with his fear of society was, that it did not trouble him much in the day, but only after supper. He suffered from involuntary emissions, and the symptoms connected with these were of such a character that he knew beforehand, by his feelings, when they were going to appear. The improvement has not yet resulted in perfect cure, but it has been sufficient to justify what was done. In several other cases the results of these operations, supplemented by various medical treatment, have been far more complete and satisfactory, bringing about a practical cure, and enabling the sufferer to return to his abandoned occupation.

VARICOCELE AND ITS RELATION TO NEURASTHENIA.

The relation of varicocele to spermatorrhœa and other disturbances of the genital system does not seem to have been clearly understood. My studies lead me to the conclusion that varicocele is a *result* of spermatorrhœa, or, more strictly speaking, of the prostatic disease of which spermatorrhœa is a complication. The irritation proceeding from the prostatic urethra causes relaxation and a wet-rag condition of the veins of the scrotum, usually on the left side.

Varicocele, when it exists, may be accompanied with sweating of the scrotum, and also with pain; but we have no evidence that it causes any important symptoms of itself, either local or general, and those who expect that a cure of this condition will cure the other symptoms of sexual neurasthenia will be disappointed. I have been consulted for a case of spermatorrhœa where there had also been varicocele, and this varicocele had been operated upon very successfully; the operation cured the varicocele, but otherwise the patient had not been at all benefited, and I see no reason why he should have been—the varicocele was a *result, not a cause,* and the treatment needed to be directed to the cause more than to the result. It is entirely proper to remove varicocele, if it be possible; but it is not well to depend upon its removal for the cure of neurasthenia, any more than it is to depend upon cutting strictures or operating for phimosis for the relief of the same symptoms. All operations of this kind are to be considered in cases where malformation exists, and are often to be performed, but always with the understanding that they are the incidents of the treatment and not the treatment itself, and it is my rule always to have this understanding with the patients, with their physicians, and their friends.

SEXUAL NEURASTHENIA IN WOMEN.

The question has several times been asked me by physicians, whether sexual neurasthenia in woman resembled that in man? The answer is clear: woman is man, pathologically; all the symptoms of sexual neurasthenia, as described by me here or elsewhere, are found in females as well as males, though they are not as frequent, perhaps, among the former. A young girl who masturbates is liable to have precisely the same symptoms that a young man will have who indulges in the same habit. I have had under my care two ladies, both of whom were masturbators, and both of whom presented symptoms which give no suggestion of any distinction in sex. Take the following cases:

Case XXXI.—A lady, between thirty and forty years of age, of a very decided nervous diathesis, presented these symptoms: dilated pupils; frequent micturition; vertigo, especially in reading; neurasthenic asthenopia (this was probably one of the causes of the vertigo); pain in the vertex. It has been supposed that this last symptom—pain in the vertex—was peculiar to woman, but, as I have again and again stated, it is often found in man. Attacks of mental depression; monophobia, or fear of being alone, combined with unnatural and excessive fear of death; averted eyes; pain in the back of the head; ovarian tenderness, and scanty menstruation.

As will be seen, none of these symptoms, except tenderness of the ovaries and scanty menstruation, give any suggestion of the sex. The appearance of the patient was more striking than the description of the symptoms. She had the symptoms of a man, although not at all masculine. With regard to causation there was no question, as it was freely admitted by the patient. In this case, also, anæmia was combined with the neurasthenia.

Case XXXII.—A lady, in middle life, unmarried, began to masturbate at a very early age—much before puberty—and kept it up, off and on, for very many years. The lady was of nervous diathesis, and there had been nervous diseases of various kinds in the family. This habit, acting upon a nervous constitution, had produced the following symptoms: aversion of the eyes; a feeling of fulness in the head; morbid fears, especially monophobia—fear of being alone; melancholia, delusions; anæmia; insomnia.

There was nothing in the symptoms that suggested

the sex. The same habit, acting on the same nervous diathesis in a man, would have produced all these symptoms. In this case, also, there was some trouble of the genital organs, just as in a man there would be trouble with the prostate gland, or varicocele. Pathologically, also, the prostatic urethra is a good analogue to the uterus. As it is almost impossible for any man to suffer from general neurasthenia, whatever be the cause, without developing, sooner or later, some trouble with the prostatic urethra, so, also, it seems to be almost impossible for any woman to suffer from general neurasthenia without developing, sooner or later, primarily or secondarily, some trouble of the womb or of the ovary. In man, the trouble of the prostate may not be of an important character; it may be far out of range of any diagnosis with the finger through the rectum; there may be no enlargement, but simply irritation, yet severe enough to make a man an invalid. So, in woman, the difficulty of the womb or ovary may be of a slight character; there may be no great congestion, no retroversion, no retroflexion, no displacement, no enlargement of the ovary, no positive inflammation, but still enough hyperæsthesia to be a constant source of irritation. Just as, in man, masturbation may expend its injurious effects, in some cases locally, inducing merely local disease, without any very great amount of general disease, so, in woman, masturbation may produce sometimes purely local effects, at other times both general and local.* In the following case the effects were mostly local.

Case XXXIII.—There had been an early habit of masturbating. The patient was of a nervous constitution. The symptoms were: ovarian irritation on the left side especially; a very considerable amount of backache; prolapsus and retroflexion of the womb; sick headaches; feelings of fulness in the head at times.

There was nothing here, except the local troubles, to suggest sex. The troubles and the symptoms, aside from the sick headaches, were of a local character. In woman, as in man, masturbation of itself, acting on a very strong constitution, does not, even when kept up for a long time, necessarily produce any serious local or constitutional effects; it is the masturbation acting on a nervous diathesis, it is the habit *plus* a nervous constitution that gives us the product, sexual neurasthenia. Strong, phlegmatic, Irish servant-girls may begin early the habit of abusing themselves and keep it up for years, with but little apparent harm. Indeed, one quite common habit with this class of servant-girls is to teach the children under their charge, with whom they are brought into relation, the habit of masturbation. I have known a number of cases that traced the beginning of their habit to this intimacy of the servant-girls with them. While the girls themselves were not injured, their victims, in some cases, have been life sufferers. The range for endurance of sexual excitation is wonderfully wide, there being, as it would appear, a far greater difference in the capacity of different persons for indulgence in this respect, than, perhaps, in indulgence in the appetite for food, or smoking, or drinking. For example, I was lately consulted by a man nearly sixty years of age, who, by a fall, had injured his spine so that his sexual power was impaired. On inquiry, I ascertained that he could still have intercourse three or four times a week, and when I stated that it seemed to me that in one who could do that there was not very much impairment, he said that for all his life he had been accustomed to have intercourse every night. On the other hand, I have seen very many cases to whom the sexual act is poisonous, who cannot bear intercourse or excitation in a natural way, even infrequently, who are injured by it, no matter how rarely performed, and to whom, therefore, marriage cannot be recommended, except with the understanding that the marital rights should be fulfilled but very infrequently indeed. For this reason, the indiscriminate prescription of marriage for cases of sexual neurasthenia is, like the indiscriminate recommendation of medicine of any kind, oftentimes unwise and unscientific.

UNDER-ESTIMATE AND OVER-ESTIMATE OF SYMPTOMS.

It is the common belief that patients suffering from this form of disease, magnify—create symptoms which really never existed. This belief is an erroneous one; there are more persons who overlook many of their symptoms, forget them, or regard them simply as signs of health, or at least not as signs of disease, than of those who create symptoms that do not exist, or over-estimate their importance. There are many, for example, who for years have had such symptoms as sweating scrotum, sweating hands (palmar hyperidrosis), mild costiveness, mild insomnia, cold hands and feet, frequent urination, abnormal erectile excitability, pain in the perineum, dryness of the hair and skin, with slow reaction of the skin, neurasthenic asthenopia, flying pains in different parts of the body, who never think of any one or all of these symptoms, do not worry over them, do not refer them to the prostatic gland, or to any irritation proceeding therefrom; who do not, indeed, regard them in any sense as evidences of disease, and never, therefore, consult a physician for them; yet all these phenomena are symptoms of a pathological state; they are not the phenomena of health. They are not usually serious or fatal, although they may, in time, lead to symptoms that are serious; they are consistent with great activity of mind and body.

There are those who, having suffered during life from these and allied symptoms, have never known what real health is; they have no means of comparison; for all they know that every one has just such sensations and experiences.

On the other hand, there are some, but they are not the majority, who over-estimate these and allied symptoms, who fear that they have impending paralysis, or softening of the brain, or some disease that shall cripple or destroy them; and these patients have been taken as the type of the class. I see both kinds—those who over-estimate and those who under-estimate the significance of their symptoms. One of the difficulties of getting a full history of cases of this kind is, that patients forget the symptoms they have passed through; so little impression have they made upon the mind that only by considerable effort can they recall them.

In those cases where hypochondria is a symptom, that is, morbid fear of disease, this morbid fear is itself a symptom, just like sweating hands and scro-

* The following passage from Erichsen, on concussion of the spine, is instructive: "A person who, by any of the accidents of civil life, meets with an injury by which one of the limbs is fractured or dislocated, necessarily sustains a very severe shock, but it is a very rare thing indeed to find that the spinal cord or the brain has been injuriously influenced by this shock that has been impressed on the body. It would appear as if the violence of the shock expended itself in the production of the fracture or the dislocation, and that a jar of the more delicate nervous structures is thus avoided. I may give a familiar illustration of this from an injury to a watch by falling on the ground. A watchmaker once told me that if the glass was broken, the works were rarely damaged; if the glass escapes unbroken, the jar of the fall will usually be found to have stopped the movement."

tum, or premature emissions, cold hands and feet—a result of the exhausted condition of the brain—and, like all these other symptoms, they disappear as the brain becomes stronger.

Those persons who intellectually over-estimate their symptoms from ignorance, are cured by simply informing them of their mistake; in such cases a single interview with a physician in whom they have confidence removes the burden of a lifetime. Those who emotionally over-estimate their symptoms from morbid fear or hysteria, will continue to make such over-estimate in spite of our reasoning with them, until such time as the brain becomes invigorated by rest, treatment, and hygiene.

The original and exciting cause in cases of sexual neurasthenia is usually irritation of the prostate gland, but many of the above symptoms come from the brain and spine, to which the prostatic irritation has extended. Such persons require, then, both local and general treatment—local treatment directed to the brain, the spine, and digestive system.

STRYCHNIA A PARALYZING AGENT.

Proofs from Authentic Experiments.

By THOMAS W. POOLE, M.D.,

Lindsay, Ont., Canada.

It was Dr. Anstie who wrote of strychnia, that it had been somewhat hastily classed as a spinal stimulant, not because it had been shown to be such, but "merely in deference to preconceived ideas as to irritability," which ideas might themselves be entirely erroneous.

"The researches of Dr. Harley were the first scientific attempts" to explain the action of this drug, and what he found was that strychnia prevents the oxygenation of the blood. This is an effect which Dr. C. B. Radcliffe states "may, in one sense, be looked upon as equivalent to loss of blood, for blood which cannot become arterial is as good as lost to all purposes of life." It is a change which, Dr. Anstie remarks, "can hardly be supposed to communicate increased force to the nervous system." ("Stim. and Narcot.," p. 72.) Indeed, if the symptoms of strychnia-poisoning, and those of impending death from sudden hemorrhage be collated side by side, there will be found a remarkable similarity between them.

It is not, however, to general considerations, but to the actual facts of physiological experimentation, that an appeal is here to be made to prove the paralyzing action of strychnia. One of these facts was mentioned in a previous paper ("Electricity a Paralyzing Agent"). It is, that in a frog poisoned by strychnia, the spasms and convulsions may be promptly arrested by the thrust of a piece of whalebone, or of a wire, into the spinal canal, so as to destroy the cord. This result, at first sight, would appear to be adverse to our thesis, since it may be said, if strychnia be a paralyzer of the cord, the destruction of that organ ought simply to intensify its effects on the muscles rather than to arrest them.

But other considerations come into play here. There is good reason to believe that the motor nerve-trunks bear, in some respects, a similar semi-independent relation to the spinal cord as the latter bears to the brain, and that when the disturbing influence of the action of strychnia on the cord is prevented, by its destruction, from extending itself along the motor nerves and paralyzing them, these motor nerve-trunks regain their former molecular state, and with this their control over the muscles.

It is easy enough to justify this doctrine. In its favor might be quoted the modern (erroneous) teaching, that the cord and its motor nerves may be found in the very opposite conditions of excitability, as when the cord is said to be excited and its motor nerves paralyzed by atropia. (Dr. Ringer: "Ther.," p. 462.) But its further and more complete justification is to be found in the fact that the peripheral nervous system does not grow from the spinal cord as branches from a tree, but that the first development of these nerves is at the periphery, and that they grow toward, and finally attach themselves to the cord. Dr. Thomas Laycock, professor of medicine, psychology, etc., in the Edinburgh University, states it to be "a general fact, deduced from clinical observation and experimental research, ... that not only do the tissues themselves undergo normal vital changes independently of nerves or of a nervous system, but also that *nerves and nerve-fibrils perform their appropriate functions independently of nerve-centres.* Nerves are produced anew in organized plasma, and join on to the general trunk in accordance with the order of embryonic development of the nerves from the periphery to the centre. MM. Philipeaux and Vulpian made numerous researches, which prove that nerves separated wholly from the nerve-centres, and completely altered as to nutrition, may become regenerated, although remaining separate, and recover all their vital properties. *Numerous experiments, also, on the nerves of muscles, show that those motor nerve-fibrils have their own inherent properties in entire independence of brain, spinal cord, or nerve-centres,* and not only in separated limbs but in muscles that have been cut from the limbs." (*Medical Times and Gazette, Braith. Retros.*, Jan., 1872, p. 58.)

With these facts before us, the foregoing explanation of the effects of pithing in arresting the convulsions of strychnia-poisoning is at least equally valid as the explanation that this operation puts an end to the stimulating action of strychnia on the cord and its motor nerves.

Having disposed of the objection which this experiment might furnish to some minds, I proceed to more direct evidence. It is unnecessary to trouble the reader with the proofs that "strychnia does not act on the muscles, the nervous extremities, or on the nerve-trunks," and that "it does act on the nerve-centres of the medulla oblongata and medulla spinalis." (Stillé and Maisch: "Nat. Dispens.") This is universally admitted. It is well, however, to point out how singularly physiological writers sometimes misinterpret the results of experimentation.

Dr. Ringer writes: "After division of one sciatic nerve, strychnia excites tetanus in every part of the body except the limb supplied by the divided nerve." Dr. R. holds that "as the vessels of this limb are undivided, its unconvulsed muscles and nerves are as much poisoned by strychnia as those parts which are convulsed." ("Therapeutics," p. 499.)

This can hardly be true. Like causes produce like effects; and where the effects differ, there must be a modification in the cause. The distal portion of the cut nerve cannot receive a paralyzing wave from the cord from which it is separated by section; so that this source of paralysis (or stimulation) is cut off. If it still holds true, as stated by Dr. W. B. Carpenter, that the membranous sheath of the ultimate nerve-fibre is not penetrated by blood-vessels, then there is good reason why this cut nerve should escape the influence of the poison, at least for a

time, and so continue to retain its control over the muscles, as a consequence of which they do not pass into spasm. The *facts*, as stated by Dr. R. are undoubtedly true, but the *inference* he draws from them is obviously erroneous, even from his own standpoint; for the foregoing considerations hold good whether the impulse passing along the nerve be paralyzing or stimulating. Here is another experiment:

"If all the tissues of the frog's leg, except the nerve, are tied, and the parts beneath the ligature protected from the poisoned blood, all parts become tetanized. But the convulsions cease sooner in the poisoned than in the protected leg, the motor nerves of the former having been paralyzed by the strychnia-containing blood." (Ib., p. 500.) False induction again! If "all parts become tetanized," it is evident that no part can have been really "protected" from the poison. The ligature on "the protected leg" has only protected its muscles, on which strychnia does not act. The nerve of this leg, which was left free, has conveyed the paralyzing wave from the cord to the muscle, which has been tetanized accordingly, just as if no ligature had been applied. But this is not all. The reason assigned why "the convulsions cease sooner in the paralyzed than in the protected leg," is that "the motor nerves" of the poisoned leg "have been paralyzed by the strychnia-containing blood." (Dr. Ringer here uses the word "*paralyzed*" no doubt quite inadvertently; he should have regarded the nerves as *stimulated*, from his point of view.) But the free motor nerve of the ligatured limb is paralyzed also, as has been shown above. It could not have escaped, owing to its free communication with the poisoned cord, and from the fact that "all parts are tetanized." What then becomes of this explanation of the earlier cessation of convulsive spasms in one leg than in the other, seeing neither has been really protected and the muscles of both have been tetanized? The explanation is defective because it is not based on the actual conditions present.

Here is the true explanation. In the ligatured limb, while the main, free, nerve-trunk has been paralyzed through its connections with the cord, the lesser motor nerves have been protected by the ligature, which, besides excluding the poisoned blood, has cut off the paralyzing wave which without it would have reached them from the cord. These nerves, then, retaining their vital activity, maintain for a longer time their struggle with muscle than do the nerves of the non-ligatured limb, which are all poisoned, and succumb early, setting free the contractile power of the muscle so suddenly and completely, that from the last spasms of life it passes almost at once into the contractions of rigor mortis. This is really how "the convulsions cease" in the limbs of animals dying of strychnia-poisoning.

I have had a double object to serve in thus delaying the reader from the main facts of this paper: first, to show him that the conclusions and explanations of the text-books, even when made with an air of accuracy and *quasi* scientific authority, are not always to be trusted, and are often erroneous; and second, to make it manifest that the theory I advocate has nothing to fear from physiological experimentation, with the facts of which, when rationally interpreted, that theory is in full accord.

The experiments just discussed prove, what indeed is universally admitted, that strychnia acts upon the muscles, from the cord, through the agency of their motor nerves. What is the character of this action on the motor nerves? Let Dr. Ringer answer.

"After traumatic and strychnia tetanus *the functions of the motor nerves and muscles are depressed: the motor nerves conveying impressions imperfectly*, and the muscles by direct galvanic stimulation contracting imperfectly and becoming stiff early from rigor mortis."

But may not this motor nerve depression be due to *excessive previous excitation*, which has exhausted the nerves? (This is a mode of explanation very commonly offered.)

Dr. Ringer says no!—and he justifies this answer as follows: "Strychnia apparently *directly depresses the motor nerves*, for large doses kill without exciting convulsions, when *the motor nerves are found to have lost their conductivity*." This "loss of conductivity," in the language of physiological experimentation, means *paralysis*. It is a state in which the nerves have "lost their power to receive impressions or to transmit them."

As a further proof that this depression of the motor nerves is not due to previous excitation, Dr. Ringer adds,—"When the sciatic nerve is divided, thus protecting the limb from convulsions"—the absence of convulsions indicating the absence of previous exhausting excitation—"the divided sciatic loses its irritability, though not so soon as the undivided nerve." (Ib., p. 500.)

These statements of Dr. Ringer, as to the depression, loss of conducting power, and consequent paralysis of the motor nerves, directly induced by strychnia, are confirmed by others. Dr. W. A. Hammond writes: "An experiment performed by myself and my friend and collaborator, Dr. S. Weir Mitchell, shows that *the action of strychnia is to destroy the nervous excitability from the centre to the periphery*." Here is the experiment:

"Under the skin of a large frog, whose left sciatic nerve was previously divided, a few drops of a strong solution of strychnia were introduced. Tetanic spasms ensued in two minutes. After forty-five minutes the nerves were irritated by galvanism. That of the left side, which had been cut, responded energetically, while no motions could be produced through the uncut one. The former (the cut nerve) remained excitable for two hours later." ("Dis. Nerv. Syst.," p. 539.)

The reasons for the exemption of the cut nerve from the poison have been stated above, in dealing with a former experiment. So long as the vital activity of the nerve remained, to be temporarily suspended by electricity, so long the muscles contracted. The uncut nerve was so thoroughly paralyzed that electricity could suspend its action no further, and consequently no additional contraction could be produced.

Strychnia is here shown to be so bad a stimulant that it so paralyzes the nerves as to deprive them of their power of conduction; and electricity is so poor a substitute for nerve-force, that it is perfectly powerless to cause a muscle to contract, unless where nervous activity is present in the nerve, and its still lingering control over the muscle may be further suspended.

Now, if the facts here shown on the authority of reputed experimenters be true—and there is no reason to doubt the facts they offer—what do we find established regarding the action of strychnia?

That it prevents the oxygenation of the blood.

That it produces effects equivalent to the loss of blood.

That, like electricity, it hastens the onset of rigor mortis.

That it depresses the functional power of the motor nerves, so that they convey impressions imperfectly.

That it "destroys the conductivity of motor nerves from the centre to the periphery." That it does this *directly*, and not simply as the reaction from previous excitation.

It will be obvious that while strychnia is doing this, it cannot be acting as a stimulant. It is precisely while acting in this way that it induces spasms and convulsions of the muscles ending in tetanus. These spasms and convulsions cannot, consequently, be due to a stimulus passing along the nerve to the muscle. The conclusion is inevitable, that, by this depression of motor power in the nerves, their functional activity is arrested, and the muscle is set free to exert its independent contractile power. No other conclusion is possible from the authentic facts of the case. There has never been any proof adduced that strychnia is a spinal stimulant, and the production of any such proof is impossible. When such proofs as these of the paralyzing action of strychnia appear at the hands of experimenters, involuntarily pledged by their early teaching, by their daily associations, by the literature which surrounds them, and, perhaps, even by their acquired reputations, to regard strychnia as a stimulant, what additional proofs of its paralyzing effect might not appear, could these prepossessions be entirely dispensed with.

And since such proofs as these are extant, what explanation have the leaders of medical thought to offer for having ignored them, and for having adhered to the figment of the ancient doctrine of a vital irritability residing in the tissues as something apart from and independent of the functional condition of these tissnes?

Here is an example, selected almost at random: "Irritability of the nervous centres is the precursor of exhaustion." . . . "The centres of respiration becoming exhausted are abnormally irritable." (Dr. Fothergill: "Antag. of Ther. Agents," p. 57.) These two phrases occur in successive sentences. Irritability is the *precursor* of exhaustion, and exhaustion is the *accompaniment* of irritability! By being "abnormally irritable" is here meant acting with undue vigor, because the condition the author is discussing is one of spasm, and it is a part of the teaching of the day that "over-activity of a nerve displays itself in spasm." (Dr. J. R. Reynolds: "Lec. Elec.," p. 24.)

But an exhausted nerve-centre cannot be generating and "discharging" an excess of nerve-force in stimulating shocks upon the muscle. This is a physical impossibility. From whence, then, comes the "preternatural stimulus" which the muscle is said to be receiving? From "the irritability," the modern Archæus, which is excited, and takes advantage of the exhaustion of the nerve-centre, and comports itself accordingly, and has in its various moods to be soothed, or stimulated, or cajoled, like the other "imaginary demon," its former prototype!

It will not do to assume (in justification of the doctrine of "irritability") that there are two kinds of nerve-force, one healthy and the other morbid, and that one of these becomes active as the other declines. There is no room for such a supposition in the entire range of physiology. This would, after all, only be a modern Archæus in disguise. Nerve-force is the product of nerve-cells, and is either present or absent. It is never in excess and in abeyance at the same time. It has no *alter ego* to take its place and mimic its functions, or exaggerate them in its absence. To entertain the idea of a weak condition of a nerve-centre, as accompanied by "increased irritability," is to regard the latter as a something apart from and independent of the proper function of the part; it is, in fact, to regard it as a substance, or entity, or Archæus, and is simply to echo the exploded notion of a by-gone age. It is time that this relic of antiquity were expunged from modern medical literature.

Like all great truths, this truth of the paralyzing character of strychnia will be found to be in complete accord with all the minor facts bearing on the subject.

"Strychnia affects paralyzed, sooner than unparalyzed muscles," writes Dr. Ringer: but even this short sentence is inexact. Strychnia does not affect the muscles, as Dr. R. himself shows; and the muscles are not paralyzed in the cases to which he refers. What he means is, that strychnia induces twitches and spasms in muscles whose nerves are enfeebled, sooner than in muscles whose nerves are acting normally. Why is this? If strychnia were a stimulant, would it not sooner excite vigorously acting nerves than enfeebled ones? But since its effect is to cause "depression of the motor nerves," nerves already suffering in this way have their vital activity more easily extinguished, and their muscles set free, than is the case with healthy nerves. The same thing is equally true of the other paralyzer, electricity. Twitches, tremors, spasms, and tetanus are all but varying stages of nerve-paralysis and of muscular freedom.

This latter fact is verified by the treatment of these states. Our "antispasmodics" are stimulants (Anstie). Dr. Hammond classes "stimulants" as the most curative agents in tetanus; while dilute alcohol is rapidly coming to the front as the best antidote to strychnia. "Dr. Huseman has confirmed the experiments of Amagat, that in cases of poisoning by small doses of strychnia, the treatment with alcohol is to be preferred to the treatment with chloral. The reason for this is that the quantity of alcohol required to neutralize the small but fatal dose of strychnia is not dangerous to life, although such may be the case from the amount of chloral administered." (*Practitioner, Amer. Jour. Med. Sciences*, October, 1879, p. 587.) The foregoing are very strong corroborative facts, which are entitled to much weight in this discussion.

But if strychnia be a paralyzer, how are its use and value to be accounted for in paralytic states? Its indiscriminate use in these cases is not commended. Peripheral paralysis is, more or less, frequently dependent upon a congestive or hyperæmic state of the nervous centres. Dr. Fothergill states that strychnia produces a contraction of the arterioles, which would account for its utility in some cases, after the manner of ergot, aconite, and other paralyzers; for this is not the effect of a stimulant on the arterial system.

Dr. Anstie believed it to be "a nearly universal rule that doses of strychnia which fall short of producing any poisonous effect, increase the activity of the systemic circulation, diffuse a comfortable feeling of permanent warmth over the body, and favor the progress of local nutrition, when this is absent." This is doubtless quite true. People do not resort to strychnia while in health, and in certain abnormal bodily conditions something very similar may be said of paralyzers like opium, atropia, and digitalis. Given a relaxed condition of the systemic vessels, with a consequent sluggish blood-stream, drugs of

this class, by a moderate depression of the vaso-motor nerves, proportionately release the arterial muscle from the dilating influence of these nerves; a contraction of the muscle follows, reducing the calibre of the arterial tubes, increasing blood-pressure, quickening the circulatory stream, sweeping along effete particles to be oxygenated or expelled, and thus producing the beneficial effects referred to by a species of *quasi* stimulation, but in reality in strict accordance with the paralyzing character of these drugs. The explanation of the minor differences in the effects of these drugs in accomplishing this general result, common to them all, is to be sought in the different portions of the vascular nervous system which they respectively assail; a subject on which, as yet, information is but very meagre.

It will be seen from this, that the *quasi* "tonic" effects of strychnia, as well as of digitalis, atropia, and other drugs, so far from furnishing an argument against the theory here advocated, admit of an explanation, on its basis, more truly scientific and physiological than is to be found in an exposition of their action which requires us to believe that while stimulating one portion of a nerve they are paralyzing another portion, or that they are constantly reversing their mode of action in first stimulating and then paralyzing.

I would like to close this paper with some passages from the late Dr. Anstie's "Stimulants and Narcotics," which lend a strong confirmation of what is here advanced; but I forbear, and simply refer the reader to the pages of that work, in which it is more than once strongly hinted that "the true action of vital force would appear to be rather that of restraining muscular contraction than of exciting it" (p. 70).

MEDICAL PRACTICE IN JAPAN, OLD AND NEW.

By DUANE B. SIMMONS, M.D.,

YOKOHAMA, JAPAN.

THE medical practice in Japan to-day is represented by two systems, the old and new, or the Chinese and foreign. Both are borrowed, as their names indicate—the former from their celestial neighbors, and the latter from Western nations.

The origin of the Chinese system dates back to a very early period, and was introduced by refugees, emigrants, and Buddhist missionaries, along with letters and the arts and sciences, while the Japanese were yet a semi-barbaric people. Until the country was opened to foreign intercourse, in 1859, the principles and practice of the healing art taught by the Chinese had undergone comparatively little change.

The wonderful progress that has been made by the Japanese since that time, in all that pertains to modern science, is too well known to be repeated here. We may say, however, that in no department of knowledge is the progress more apparent than in the theory and practice of medicine. Not only is every encouragement possible offered by the Government for its study, but the medical officers in all departments directly under its control are required to practise the foreign system, and all who propose to enter upon the profession from *this time* must pass an examination before censors appointed by the chiefs of the prefectures where they reside. The Imperial College, at Tokio, has a corps of twelve German professors, and the course of study, including the German language, is ten years. A course of three years, conducted by Japanese professors (for the most part educated in Europe) and in the Japanese language, has also been instituted in the same school for those who have not the means to complete the extended one under foreign teachers.

Nearly every prefecture and all the large cities have hospitals conducted on the general plan of Western nations, one of which I had charge of for eight years. A portion of these only, however, have foreign teachers.

Private enterprise has translated into Japanese, from the European languages, one or more books on the various branches of medicine and surgery and collateral sciences. Among these are some large works, such as Gray's "Anatomy" and Tanner's "Practice of Medicine." The majority of the translations, however, are compendiums like Neil and Smith and Hartshorne's "Essentials of Medicine," the latter having a very extensive circulation, exceeding by far any of the others. There are also a number of medical journals published in Japanese, and a translation of Cutter's "Physiology and Hygiene" is one of the text-books ordered by the Government for all the public schools in the empire. Notwithstanding this, a vast majority of all the doctors of the country, or about seventy-nine per cent., still adhere to the practice of the Chinese system, and will continue to do so for many years, from the fact that the Government requires *no qualification of those who have been in practice up to the present time*. The worst feature of this mistaken policy is that by far the greater portion of these are the merest pretenders and quacks of the worst sort, ignorant often not only of the Chinese characters in which the medical books are all written, but of their own written language.* For this reason we find the medical profession in former times held at a very low estimate, and so it is still, by the great mass of the people.

Worthy of no confidence, it receives none, and consequently a protracted case of illness is almost sure to pass through the hands of a number of doctors whose names, even, I have often found the patients unable to give. For slight ailments, however, a vast majority of the people patronize the numerous medicine-shops, whose keepers usually belong to the class of *irresponsible* medical men already referred to, and who "counter prescribe" for their customers, or supply them with some of the numerous nostrums which are everywhere for sale in great numbers. Professional services are not paid for by a fee, but by the profit derived from the medicine furnished. Hence, each doctor does his own compounding and dispensing. Unfortunately, custom requires him to charge by the day for medicines, the rate of which is fixed, in some localities, at from four to six cents. This is still the custom with the old-school doctors, and prevails in the rural districts and to some extent in the cities. As a natural consequence, great economy has to be exercised in the mode of prescribing. Hence, no tinctures or mixtures requiring bottles and corks are used, but all medicines are dispensed in the form of pills, powders, and little packages of roots and herbs, to be made into infusions by the patients themselves. Instead of boxes

* I have long urged on this Government the necessity of protecting its people from this class of doctors by requiring of them at least an elementary knowledge of the principles of scientific medicine. Though I feel quite certain that a majority of the Cabinet would be glad to do so, it hesitates, because of the opposition it would be sure to meet from quite a number of physicians of the Chinese school, who still find favor with not a few of the members of the Imperial court.

for pills and ointments, small clam-shells are used. Very small pills is a favorite mode of administering all medicines which can be made into them. Their manufacture is followed by some as a business, to whom the doctors send the mass to be treated. For this purpose a somewhat ingenious contrivance is used, consisting of copper plates perforated with holes of various sizes. The mass to be made up is firmly pressed against these plates till portions protrude through the holes, when they are cut off by a single sweep of a thin-bladed knife and the bits rolled round in the palm of the hand with the ends of the fingers. As the drugs used are not often very powerful, this mode of manufacturing them into pills is sufficiently accurate for all ordinary purposes.

The expensiveness of foreign drugs, and the necessity of using bottles and corks, has led to the abandonment, by the doctors of the new school, of the day system of charging for medicines, and the adoption of the one of taking pay for each prescription, so that their profits have been largely increased—some collecting as high as two or three thousand dollars a year, whereas the old-style men rarely ever succeeded in making more than a living, and a poor one at that.

Some of the new-school men have also attempted to demand a fee from their patients. In all but a few cases, however, this has been abandoned, for, though the people are willing to pay dear for foreign medicine, they object to any other mode of professional compensation (except to foreign doctors) than that embraced in their price. Well-to-do and grateful patients, however, usually present their doctor with small sums of money, but more often this gratuity consists of a box of eggs, a fowl, or a small piece of silk or cloth.

The doctors of the feudal lords, however, occupied the position of retainers, and received a stipend in rice sufficient for their support. These in turn repaired daily to the castle, and remained in attendance till relieved by others. Their duties were to look after the health of the whole household, and especially that of the Prince, whose pulse, in both arms, was daily long and carefully studied, this being the principal and almost only means, according to the Chinese system, of diagnosing disease.*

If by chance the doctor should find him ill, great solicitude immediately fills the minds of all his numerous household and retainers. This was especially exhibited in the elaborate ceremonies to be gone through with when a consultation was called. My own experience on these occasions has been exceedingly interesting, though hardly of a nature to admit of detailed description in a medical journal.

A fact worthy of notice, however, is that on every occasion the patients were found to have studiously avoided the use of water—even for washing the tips of the fingers or cleaning the teeth; the hair, beard and nails were never cut, or the latter cleaned till convalescence was established. If the illness has been a protracted one, the condition of the patients may be better imagined than described—a condition which was strangely constrasted with the exquisite cleanliness of the apartments, the richness of the silken garments and entire bed and bedding of the same material. There is no custom more deeply rooted in all classes of Japanese than this one of not washing when ill. Even the doctors of the new system refrain from insisting on personal cleanliness in their patients as a hygienic measure, as their dismissal would almost certainly be the penalty.

The old-school men also never permit their patients to drink cold water. Great attention is paid by them, however, to the diet, even in mild cases; and when the disease is severe, all food except soft-boiled rice (so diluted with water that it can be drunk) is forbidden for days together. Stimulants and tonics in any form are never administered, no matter what the form or stage of the disease. Hence it is that nearly as many sick die from inanition as from the disease, a fact admitted by all who have come over to the new system and adopt the supporting plan in the management of their cases.

It is impossible to estimate the deleterious effect of this starvation plan of treatment of diseases of all kinds in a country where a purely vegetable diet is next to universal. No wonder, we may add, that the population of this empire has fallen far short of the normal rate of increase observed under much less favorable circumstances of soil and climate.

Though this would appear to be the place to give a description of the theories of the Chinese school of medicine, we shall not enter upon it now. Suffice it to say that, in its elaboration a perverted system of thought has led its disciples to waste intellect and opportunities in groping after tortuous explanations of natural and morbid phenomena, and the complex relationship of the five pseudo-elements of Chinese philosophy.

The therapeutics of the Chinese school, however, is more rational, in that experience has led its disciples to use a variety of drugs of undoubted efficacy in disease, such as cathartics, diuretics, diaphoretics, sedatives, astringents, antispasmodics, emetics, etc., some of which, if not already adopted by Western nations, might form valuable additions to its materia medica. For example, the use of aconite (lately lauded so highly in the West for certain forms of neuralgia), and of mercury in syphilis, is undoubtedly of Chinese origin. So universal has it been the custom of the disciples of the old school of medicine in Japan to use mercury in the treatment of all venereal sores, that, in nearly twenty years of hospital and private practice among the natives, I have rarely met with one who has ever had a chancre, who has not been thoroughly mercurialized by stuffing the nostrils with cotton or paper saturated with the drug.

Most of the doctors of the new or foreign system, however (who, by the way, reject everything good or bad in the old), have, for the most part, not only abandoned this mode of treatment of syphilis, but have gone to the other extreme of not using mercury in any form, relying entirely on iodide of potash for its cure in all its stages. With the generally accepted opinions as to the value of this drug in the treatment of this disease, there is little doubt but those suffering from it will, for a time at least, gain little by this change of practice.

In surgery, even prior to the opening of the country in 1859, the Japanese had made some feeble attempts, and a few monographs are met with in which individual efforts in this direction are detailed, and even illustrated. Tumors of the breast and lipoma, when seated on the back and shoulders, were attacked by the knife. Quite a number of minor operations, such as the strangulation of hæmorrhoids and fistulæ by the ligature, and even paracentesis of the bladder for retention of urine, were occasionally performed. Most, if not all those who had attained

* This practice is still carried out with the Emperor by a staff of ten of the leading doctors of this capital, each receiving a monthly salary of about $200. Though these are all physicians of the new system, some of H. M.'s household, it is said, still have little or no faith in them, and send for the adherents of the Chinese school when ill.

this proficiency, however, had been students of the Dutch surgeons who were stationed at Nagasaki. Very soon after the country was opened, some half-dozen men were sent to Europe to be educated in medicine. One of these, on his return, founded a private hospital in Tokio, and has done some very creditable work as an operating surgeon.

Obstetrical practice in Japan is in the hands of professional midwives. When labor commences, the patient is placed on her knees, supported by a pile of cotton mattresses at her back. The midwife presses down upon the abdomen during the pains, in aid of the expulsive effort. The patient is allowed gradually to assume the recumbent position, and on the twentieth or twenty-first day, if all has gone on well, takes a bath and resumes her duties.

I see that both pressure on the uterus during labor, and an elevated position of the head and shoulders after confinement, are being advocated by some of our Western obstetricians.

It may be remarked here that I have never seen a case of puerperal fever in Japan. It would be too much to say it never occurs; but, unless rare, it would most certainly have been encountered in daily consultations for over ten years with the native doctor, in grave cases of all forms of disease. It is an interesting question as to how much the position referred to, by favoring the free discharge of the lochia, may have to do with this apparent rarity of septic poisoning in lying-in women. Version has long been resorted to by the Japanese doctors, also hooks, wires, strings, etc., for effecting delivery when the natural efforts failed of its accomplishment.

The numerous mineral and hot springs of the country are patronized by thousands for the relief of a great variety of diseases, especially for those of the skin, syphilitic and rheumatic affections, and leprosy. Quite as much harm as good is often done, however, by their too frequent use, when the water is at a very high temperature. A domestic remedy of very extensive application for muscular pain, or, as it is more commonly expressed, a tired feeling in them from any cause, is pinching, kneading, and tapping with closed fists. To this business almost the entire blind population, both male and female, devote themselves, and from their dress and well nourished appearance have no lack of occupation. Moxæ are also applied for a great variety of supposed diseases, usually as a counter-irritant, but sometimes as a revulsive; thus, for pain in the head a moxa is oftener burned on the tip of the great toe. For neuralgic pains, acupuncture is practised, and with good effect in many cases—occasionally, no doubt, by the accidental puncture of a nerve-sheath, thus relieving it of pressure from accumulated serum. In two cases I have known alarming symptoms to have occurred from the deep penetration of the long, slender needles used for this purpose, between the cervical vertebra.

Cremation in Japan.—Miss Bird, the author of "Unbeaten Tracks in Japan," visited a cremation-ground at Kirigaya, where a large number of cremations are constantly going on under the direction of Buddhist priests. The crematory is a plain building with a high roof and chimney. The bodies are placed on granite supports and fires of faggots built under them. The bodies are reduced to ashes in the course of twelve hours, and, owing to the height of the chimneys, there is no offensive smell. The cost is very slight, being only from seventy-five cents to three dollars.

DISLOCATION OF THE ACROMIAL END OF THE CLAVICLE DOWNWARD.

By J. X. ALLEN, M.D.,

OGDEN, UTAH.

This dislocation is extremely rare—so rare, indeed, that Professor Hamilton declares there are but three cases recorded, one described by Melle, in 1765, the second by Fleury, in 1816, and the third by Toomel. I not only had never seen this singular dislocation, but had never considered it possible until my attention was called to the case which I am about to lay before your readers. A little reflection will show how extremely difficult it is for a force to be so applied (without producing a fracture or dislocation of a frailer or contiguous bone or articulation) as to compel the acromial end of the clavicle to pass down by or through the coracoid process. In its descent it must not only break down the coracoid process, but must rupture in its course the acromo-clavicular and also the coraco-acromial and coraco-clavicular ligaments, until it finally finds a resting-place below the acromion process.

Near the middle of November, 1880, Miss E., of Brigham City, Utah, was brought to my office for treatment. She said that some six weeks previous, while in the act of splitting a stick of kindling wood, and while the hand which held the axe was extended upward and outward, and at the moment when she intended to precipitate the utmost strength of her arm in a final blow, something gave way in her shoulder. The axe dropped from her extended hand, and her arm hung lifeless at her side, while the most terrible lancinating pain shot through her shoulder and radiated in all directions, but more especially in the vicinity of the acromial end of the clavicle. She was a beautiful young girl, of some sixteen or seventeen years of age, of almost perfect muscular development and symmetry, and was nearly heart-broken over the deformity, which she had been assured would continue so long as she lived. Previous to her visit at my office she had been under the treatment of a professional "bone-setter" in her native town, after which she was sent to a hospital in Salt Lake City, where she had the attention of a respectable regular practitioner, but who at length confessed he could do nothing for her.

On examination, I found a marked depression over the coracoid process, and the inferior angle of the scapula was thrown prominently outward. There was a great deal of discoloration in the region of the axilla. There was complete immobility of the arm when dependent on her volition, nor could she so much as move a finger without assistance, nor flex the hand at the wrist. I had no trouble in moving her arm at the shoulder, but it gave great pain. There was no crepitus. A pricking sensation constantly pervaded the arm and hand, which were turgid and swollen. To use her own language, her hand felt "as if it was asleep." The arm and hand were cold, and there was an entire absence of sensation. But the most singular thing about the whole affair was that, though there was a depression over the region of the coracoid process, yet the shoulder was elevated some three inches above its fellow. The angle at the neck was not higher than the opposite side, but a line drawn from that angle to the tuberosity of the humerus was the hypothenuse of a triangle whose perpendicular was three inches. There was positively no fracture or luxation of the humerus to account for the elevation. The radial

artery was normal in its stroke at the wrist. A line drawn from the centre of the spinal column to the tuberosity of the humerus was one and one-eighth inch less on the injured side than on the other.

The more I surveyed the subject the greater appeared the mystery. I therefore despatched a messenger for my friends, Drs. J. D. Comahan and A. S. Condon, of this city, for consultation, and both were promptly on hand. They instituted a careful and searching examination. Our diagnosis was that the clavicle had been dislocated downward in its acromial end. My assistants drew the shoulder outward and backward, while I tried to seize and disengage the clavicle. In this manner the dislocation was easily reduced. Afterward we applied a broad band around the chest, under which and over the scapula was placed a thick, firm linen pad, and over these was applied a figure-eight bandage, to draw the scapula inward to the body and keep the shoulder *in situ*.

For several days I used a weak current of electricity to restore nerve-vitality. She continued to wear the appliances for some time, but rapidly regained complete use of the arm, and up to the present time it has given no trouble.

In conclusion, I would ask, if this was not a dislocation of the acromial end of the clavicle downward, what was it? It is for the opinion of readers of the RECORD that I present this paper. The diagnosis of fractures and dislocations would be easy enough if victims at the time of accident would be careful to observe some uniformity, and do it in conformity to some old established law or principle upon which could be predicated some rule for their reduction. But in the excitement attending accidents their thoughtlessness give the surgeon no end of trouble.

THE VITALITY OF GONORRHŒAL VIRUS.—Dr. E. T. Rulison relates an interesting case in the *Medical and Surgical Reporter*. On July 17th a patient called with symptoms of gonorrhœa. He gave the following history: He became acquainted with a young lady visiting in the village, and was invited to call. The invitation was accepted, and also another of a different character, the same evening. This was the first and last time that he had ever had sexual intercourse. At first he improved under treatment. Then he got worse. The fluctuations in his condition continued for several weeks. Finally he left the village, and soon after reported himself well. After a few weeks he returned to his village and resumed his vocation. His trouble began again at once, and kept on getting better and worse as it had done before. At last the patient came in one evening and said he had found out the trouble, and felt positive that the end had come. When first taken he got some of the discharge on his pants, and he remembered that whenever he wore those pants and was well enough to get along without bandaging, he got worse again at once.

THE CONVICT, DR. BUCHANAN.—Buchanan, the foster-father of bogus medical diplomas, entered the Eastern Penitentiary at Philadelphia a few days ago with his head covered by a sack to prevent his knowing the location of his cell. He had been confined up to that time in the County Prison, but now he is a convict in the Penitentiary, fulfilling the sentence passed upon him for conspiracy to defraud the United States of his bail. There are still other charges pending against him. Thus ends for the present the career of the celebrated "doctor."

Progress of Medical Science.

A RARE CASE OF BULLET IN THE BRAIN FOR SIXTY-FIVE YEARS.—Dr. Robert Elliot has reported this interesting case in the *Edinburgh Medical Journal* for December, 1880. The patient was shot in the left eye at the battle of Waterloo, in the year 1815. He instantly fell, and was reported as dead by his right-hand neighbor, Sergeant Morris, who makes the statement in his "Recollections of Military Service," quoted in the obituary notice of the patient's death, which occurred at the age of eighty-five. The patient came under Dr. Elliot's observation some thirty-three years after this remarkable escape from death. After careful inspection of the scalp and manipulation of the cranium, he could not observe any indication that the ball had anywhere effected an exit from the cranium. The feelings described were such as would be expected to arise from a bullet that had destroyed his eye and traversed the brain, but had not effected its escape. He never varied in his description of the sensations experienced when he lowered his head, or (when it was down) he turned it from side to side. Dr. Elliot had no reason to doubt the accuracy of observation and judgment of the patient, whom he considered honest and intelligent. This case resembles that of a young military officer (*Dublin Journal of Medical Sciences*, 1830) in whose hands a gun burst, and so fearfully fractured his skull in front that portions of the bone and brain had to be removed, yet the young man recovered and lived for several years, and at last died of fever. In this case a post-mortem inspection of the head was obtained, when it was found that some two or three ounces' weight of the shivered lock of the gun had actually been ensconced in the anterior portion of the brain for some two or three years without obvious or recognized impairment of the faculties ascribed to the mental organs.

DETECTION OF ARSENIC IN WALL-PAPERS.—Dr. William B. Hills excepts to the wide publicity given to the nitrate of silver as a test for arsenic in wall-papers. In the *Boston Medical and Surgical Journal*, January 13, 1881, he asserts that it is one of the *least* reliable tests for the purpose mentioned. The cases in which the nitrate of silver test gives fairly reliable results are comparatively few, and are essentially those in which arsenite of copper (Scheele's green) or aceto-arsenite of copper (Schweinfürt green) is used as a pigment, unmixed with other substances. These arsenical compounds are, however, seldom thus used, but are commonly employed in combination with other substances, by which means the green color is modified and various tints are obtained, in which, as a rule, the arsenical green cannot be detected by any physical appearance. Under these circumstances the above test will ordinarily fail to indicate the presence of arsenic, and particularly so if the arsenical green be mixed with organic pigments. Many of these latter, when treated with ammonia, furnish colored liquids, the color varying with the nature of the organic pigments. If nitrate of silver is added to such a liquid, any precipitate produced, whatever its true color may be, will ordinarily assume the color of the liquid. For example: yellow arsenite of silver will usually *appear* red in a red liquid. Obviously, no conclusion can be drawn in such cases as to the presence or absence of arsenic. Again, the yellow

sulphide of arsenic is sometimes used, and the arsenic in such cases cannot be detected by nitrate of silver. The test is also useless in detecting arsenious acid in the aniline colors. Dr. Hills' method of proceeding is as follows: take a sample three or four inches square, cut into small pieces, moisten with concentrated sulphuric acid, and heat carefully until the paper is thoroughly charred. Let the charred mass cool, add to it about one fluid ounce of water, grind up the black mass so that the water may come in contact with all parts of it; filter and wash. The arsenic will be found in the filtrate, which is examined by Marsh's test. All chemicals must be free from arsenic. A paper which, treated carefully in this manner, furnishes no arsenical stain on porcelain does not contain any appreciable amount of arsenic.

The Immediate Cure of Inguinal Hernia by a New Instrument.—Dr. W. Dunnett Spanton has published in the *British Medical Journal*, December 11 and 25, 1880, a paper on this important subject, in which he proposes to obliterate the inguinal canal by means of a screw-like instrument shaped like a corkscrew, with a flat point and movable handle. The screw is made rather broader near the point, tapering somewhat toward the handle, and should be sufficiently strong not to break; but yet as thin as may be consistent with strength. In addition to this instrument a thin, strong knife, like a tenotomy-knife, is used, for separating the skin from the subjacent tissues. The mode of performing the operation in a case of ordinary oblique inguinal hernia is as follows: an incision is made in the skin of a scrotum large enough to admit the forefinger easily, over the fundus of the hernial sac, generally about two inches below the spine of the os pubis; and the skin is separated from the parts beneath by means of the blade or handle of a narrow scalpel, to an extent determined by the size of the hernia, and that of the inguinal canal. The operator standing on the left-hand side of the patient, the forefinger of the left hand is passed up to the internal abdominal ring, invaginating the fascia and hernial sac to the same extent. A careful examination is now made of the surrounding structures, the position of the vessels clearly made out, the size and shape of the abdominal rings noted, as well as the length of the canal. This is necessary in order to have an instrument of the proper size. The left forefinger, being retained in the hernial canal, protecting the spermatic cord and, at the same time, closing the internal ring, the screw instrument, previously dipped in carbolic oil, is, with the right hand, thrust through the skin of the groin so as to transfix the aponeurosis of the external oblique muscle, at a point somewhat above that at which it is intended to pass through the conjoined tendon. Having given the instrument one half turn to the right, if a right inguinal, and a whole turn if it be a left hernia, it is next made to pierce subcutaneously the conjoined tendon of the internal oblique and transversalis muscles as high up as can safely be reached, the left forefinger carefully guarding the point so as to avoid wounding the vessels or peritoneum. This part of the operation must be executed cautiously and deliberately. It will then be found that, as soon as a hold has been secured by the instruments, the internal ring is practically closed. Another turn is now given to the screw, causing it to pass through the invaginated tissue—whether consisting of fascia, or sac, or both—and it is again passed through the external pillar, and then across to the internal pillar of the external ring, and another turn given if possible, so as to bring the point out at the wound in the scrotum. The handle should then be flatwise on the abdomen, and the point of the instrument be protected by a round piece of solid india-rubber, or by winding around it some carbolized gauze. A light pad is then placed over the part, and a bandage applied. The subsequent treatment is very simple. After a period, varying from a week to a fortnight, a certain amount of inflammatory action will be observed along the line of the inguinal canal where the instrument lies, and more or less discharge takes place from the wounds. The amount of induration excited will be the guide as to the time for removal of the instrument; but a week has usually been found sufficient. The removal of the instrument is easily effected, as the suppuration which takes place along its course serves to loosen it somewhat, and by keeping it well oiled from day to day, it is easily withdrawn. The wounds will readily heal under any simple dressing, with pad and bandage. In thirteen cases thus far operated upon, not one had any serious symptom to be recorded. In eleven cases the cure has been complete.

Case of Strychnine-Poisoning Treated Successfully with Bromide of Potassium and Chloral.—A case of strychnine-poisoning has been reported by Dr. Engledue Prideaux (*Lancet*, January 8, 1881), in which the hydrate of chloral and bromide of potassium were successfully used as antidotes. The poisoning occurred under the following circumstances: at an institution with which Dr. Prideaux had been connected there was a mixture kept, containing among other ingredients a solution of strychnia, of which there were five minims to the ounce of water. The dispenser had, by mistake, substituted ounces for drachms of the solution of strychnia. The patient who received the medicine was a woman about fifty years of age, who had been out at work in the open air all day. She took of the medicine about two ounces after her meal, "to make up for not taking any during the day," as she said. When the doctor saw the patient, he found her lying on the floor, unable to speak, perfectly rigid, and in a condition of constantly recurring opisthotonos, convulsions succeeding one another with great rapidity. The pulse was slightly quickened, but otherwise normal. As soon as the jaws were relaxed he administered half an ounce of potassium bromide in solution with one drachm of chloral. After a quarter of an hour the spasms began to materially abate, and the muscles relaxed in a marked degree. Again he administered another half-ounce of the bromide, and in half an hour there was almost perfect relaxation, slight spasms recurring at much longer intervals. After remaining with the patient for some time, and finding the spasms did not recur in their intensity, but were becoming much slighter and only occasional, the doctor left, ordering another ounce of bromide to be given in divided doses of two drachms every four hours during the night. The next day the patient was in a very feeble state, and quite unable to raise herself and hardly able to move a muscle; indeed, she seemed like a sheet of wet blotting-paper, and was almost completely paralyzed; her water was voided in great excess, and also a large quantity of liquid fæces. The pulse was slow and markedly feeble. She had taken half of the remaining quantity of bromide. Its administration was then stopped, and she was ordered strong beef-tea and milk, with a little brandy at frequent intervals. After three days

she was able to raise herself, and had regained power over the sphincters, and on the fifth day was able to sit up. She then rapidly recovered. The patient must have taken about eighty minims in all, nearly three-quarters of a grain of strychnia. The complete muscular paralysis was attributed to the partial abolition of the functions of the spinal cord, caused by the exhibition of the remedies, and not to nerve or muscular exhaustion consequent upon the extreme excitation and activity induced by the poison.

Case of Recurrent Pemphigus Puriginosus due to Checking of the Menses.—Dr. W. A. Duncan has reported an interesting case of this character (*Lancet*, January 8, 1881) in a patient aged twenty-five years, who had, by exposure to the rain on the second day of her monthly period, been wet through. Next morning the patient noticed that the menses, which had commenced the previous day, were stopped. She then complained of headache, nausea, and general malaise, together with a peculiar tingling sensation in both hands. When the patient came under observation, Dr. Duncan noticed numerous round papules on the palmar aspects of both hands, and also on the sides of all the fingers. The hands were somewhat swollen and slightly œdematous, but the skin was not inflamed. The sensation of pricking and tension was so great that the patient could obtain no sleep without the aid of a morphia draught. The papules subsequently developed into vesicles, which, in irregular groups, were situated most accurately over the course of the median and ulnar nerves on the palms and fingers; even the small palmar cutaneous branches of both of these nerves over the anterior annular ligaments had their appropriate vesicles. The next day these vesicles had developed into round bullæ, from a quarter of an inch to half an inch in diameter, and contained a perfectly clear, colorless fluid. On the palms the bullæ were much less developed, the largest being about the size of a pea, which gave the patient great pain. These disappeared under local treatment with vaseline, poultices, and a lotion of lead and belladonna; but, notwithstanding every possible precaution was taken to avoid catching cold, the menses again stopped suddenly during their regular appearance. Several papules appeared upon the sides of the fingers, and a few on the palms. The swelling and irritation were not so severe as on the first attack. The patient was then ordered to the sea-shore, and put upon the citrate of iron, phosphorus, and zinc, for several weeks, with a satisfactory effect.

On the Treatment of Othæmatoma.—Dr. William Meyer (*Archiv für Ohrenheilkunde*, XVII., 2) recently resorted to the treatment for othæmatoma by the method introduced by Metzger, with excellent results. This system consists in systematic kneading of the effusion to assist absorption, and the application of a pressure-bandage, which is worn continuously. In three cases reported in the *American Journal of Otology*, January, 1881, in which this was tried, the result was very satisfactory. The first case was that of a man aged thirty-four years, strong, not plethoric, and perfectly healthy. His father, however, was insane (religious melancholy) at sixty-four years of age, and died a year later. One and a half month before the patient applied for treatment, without any previous injury of any kind, a hard, insensitive nodule appeared on the left auricle, which increased in size gradually, and developed fluctuation without any change in the skin, and without pain, tension, or sensitiveness. The tumor was incised, and dark fluid blood evacuated. From this time the cavity filled rapidly, became sensitive, and was accompanied by headache. It was again incised three days later and the cavity stuffed with charpie, but the pain increased, extending to the temple, vertex, and nape of the neck. On examination by Meyer subsequently, in addition to the hæmatoma, the whole auricle was much inflamed, and this inflammation was first reduced by continuous applications of lead-water. Massage was then resorted to four times a day, and continued for a quarter of an hour each time, the skin being first anointed with glycerine salve. In the intervals the auricle was kept firmly compressed between masses of charpie, by means of a bandage over the head. Massage was stopped as soon as it produced pain, but, except the first day, was well borne for the whole fifteen minutes. One week after the hæmatoma had almost disappeared the skin was freely movable on the cartilage, but there was a slight thickening of the ear. Massage and the pressure-bandage were continued for some weeks. Ten weeks after treatment the auricle was absolutely perfect, except a very slight thickening. The second case was in the same patient, but on the right auricle, one and a half year later. The tumor began in the same way, and the diagnosis was confirmed by aspiration. The same treatment was used, but only twice a day, and in three weeks the ear was well, and both auricles were perfect four years after. The third case was in a woman, aged thirty-four years, and the tumor was the result of a blow. She was perfectly healthy, but her mother had been insane. The same treatment was used, and the tumor had almost disappeared when she withdrew from observation. In all these cases external evidence of a degeneration of the cartilage was lacking; the existence of any predisposing disease was absent, and the only cause to be discovered was in the history of the patients, in both of whom the parents had been insane. Hun's observation, says Meyer, that the appearance of othæmatoma in sane persons usually precedes a later mental disturbance, and Roosa's, "that although persons suffering from vascular tumor of the ear may not always be insane, they generally have brain disease," is worthy of special attention in this connection.

Impacted Fæces.—Dr. Robert Battey has a practical way of relieving women of hard masses of impacted fæces when for any reason an enema or cathartic fail to do the work, or cannot be administered. Instead of distending the sphincter ani muscle and digging out the mass with a spoon, or with some like instrument, he breaks it up and presses it out by means of the fingers in the vagina. This may generally be accomplished without difficulty, or with as little difficulty as by other means. The method is, moreover, less disagreeable, both to the doctor and to his patient. It would manifestly be more easily accomplished in the cases of women who have been or are parturient.

Small-Pox in Jersey City has been increasing of late in a way to alarm the authorities. In the country at large there seems to be a considerable prevalence of the disease, though during the first week in February there were more cases in Philadelphia than in all other places put together. Seventy-one deaths were reported for the week ending February 5th. Of these, 47 occurred in Philadelphia, 9 in New York, 13 in Chicago, and 5 in San Francisco.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 19, 1881.

THE ABOLITION OF THE OFFICE OF CORONER.

The successful working of the Massachusetts law abolishing the office of coroner, and transferring its duties to a medical expert, has had its effect in stimulating other States to a like reform. The question has often been asked regarding the real usefulness of the coroner in our body politic, and the same question is now likely to be repeated during the present session of the State Legislature in discussing the practicability of altering the methods of procedure in cases of sudden death associated with suspicions of the commission of crime. No one who has studied the subject of coroners' investigations—none who have watched the proceedings of the juries by the present law whereby a verdict is rendered in cases of sudden death, can fail to be convinced of their utter uselessness. In fact, the more the matter is looked into the more absurd does the present system appear.

Mr. Clark Bell, a member of the bar of this city, in an able address before the recent meeting of the Medical Society of the State of New York, brought this subject to the attention of the profession throughout the State, and it is to be hoped that practical good may come from his effort. The Medico-Legal Society of this city, after concluding upon the necessity of a radical change in our present laws relating to the office and duty of coroners, appointed Mr. Clark Bell and Professor Frank H. Hamilton a committee to bring the subject before the State Society, with a view of obtaining the aid of that body in influencing the necessary legislative action. Thus the proper beginning was made, and the endorsement on the part of the State Society of the necessity for a change in our present laws was timely and wise.

From the time that Mr. Tyndale, of the Boston bar, practically opened the discussion before the Department of Health of the American Social Science Association, at its meeting in 1877, until the present, the medical profession of the country has interested itself more or less directly in the propositions for reform advocated by that gentleman. In Massachusetts, as a result of the powerful influence of the medical society of that State, the Massachusetts law abolishing coroners' inquests was passed, and the people of this State have thus offered to them a useful model by which to guide them in what now promises to be a serious and deliberate determination to make necessary reforms. The Massachusetts law was passed on May 9, 1877, and since then its practical working has given universal satisfaction to the citizens of that State. In estimating the agencies which effected this result, it is proper to state that the *Boston Medical and Surgical Journal*, from the first inception of the movement, tendered its powerful support, and made the profession of the State a unit of influence in the proper direction.

The history of the passage of the Massachusetts law should be an encouragement for the medical profession of this State to take hold of the matter in earnest, with the reasonable hope of being likewise successful. Appreciating what such an influence can accomplish, Mr. Clark Bell has sought it in his appeal to the State Society, and it is fair to assume that the desired result in the shape of a new law will be speedily obtained.

The measures proposed are the abolition of the office of coroner, the dispensing with juries in preliminary examinations, and the adoption of a system by which a competent medical examiner shall be appointed in the different districts of the State, whose duty it shall be to examine into the cause of all sudden deaths, and in cases of suspected criminality to report to proper officials, who shall examine into and report upon the legal and statutory aspects of the charge. As the best reasons for such a change, it is claimed that the examination by the coroner and the verdict of his jury have no weight whatever upon the subsequent judicial proceedings—in fact, very often actually interferes with the course of justice, on account of incompetent autopsical examinations. Admitting this fact, which is eminently proper in the light of experience, the trial by such a jury can easily be dispensed with without infringing upon the rights of any citizen suspected of crime. Besides this, the alleged criminal has the privilege of being tried by two other juries—the grand jury, before the indictment, and the jury of the court, after the indictment. The final trial is, after all, the most important, because entirely independent of previous judicial proceedings.

Thus, it will be seen that practically the right of trial by jury, so dear to every one, is not infringed upon.

Again, it is claimed that an ordinary coroner's jury is entirely incompetent to form a verdict in the large majority of cases which are the subject of legal inquiry. In the first place, the law makes no require-

ments for special skill in the coroner who makes the examination, nor does it insist that the medical examiner shall be competent to discharge the grave responsibilities of his office in determining whether or no a death in a given case was the result of a criminal agency. The determination of the cause of death lies at the foundation of all subsequent proceedings, and an autopsy by a thoroughly competent medical man, or, as the Massachusetts law requires, "an able and discreet man learned in the science of medicine," is a necessity. The opinion of the medical man as based on a carefully conducted autopsy naturally becomes of value throughout the whole progress of the case, and is received as so much scientific testimony in the court.

The next question, as to the culpability of the suspected criminal, is an entirely judicial one, and a coroner's jury, as at present constituted, is no more competent to render a verdict concerning it than it is in the first step of inquiry relating to the actual cause of death. We are narrowed down to the conclusions that the real cause of death in any given case can only be determined by a medical man, and that the judicial proceedings in cases of suspected murder should be intrusted to none but the proper officer, whose duty it should be to conduct it to the proper tribunal. These are certainly simple, safe, speedy, and satisfactory ways of bringing such cases to justice, and must commend themselves to the good sense and the earnest indorsement of every good citizen.

These principles, upon which reform should be based, can stand on their own merits, and be entirely irrespective of the positive abuses so notoriously associated with the office of coroner. It need not be said here that at present the office of coroner is a purely political one, that as a rule it is filled by persons who are utterly incompetent to conduct the necessary examinations, that in many instances the autopsies are made in a hurried and unsatisfactory manner, and from a scientific and judicial aspect are valueless, and that there is no guarantee that there will be any reform in these respects until the necessary changes in the present laws are made. The movement has already commenced in that direction. It is safe to say that the medical profession is in earnest in its advocacy of the new measures proposed, and will gladly use its influence in the right direction, when the new bill is before the Legislature.

REWARD TO A SURGEON.

A few weeks ago we recounted the death of Dr. Wilbur F. Sanford, of Greenpoint, from diphtheria, caused by trying to clear out a tracheotomy-tube with his mouth. An instance of the same kind of reckless devotion, but with a very different ending, occurred in England. A lieutenant of the Tenth Regiment, being in danger of death from diphtheria, Mr. Henry Grier, the army surgeon, performed tracheotomy and then applied his own mouth to the tube to restore respiration. The patient, unfortunately, died, but the surgeon sustained no ill-consequences. For this act the Albert medal was conferred upon Mr. Grier.

The cross of the Legion of Honor is given for such deeds as these in France, and gold medals are struck for them in England. In the Land of the Free and the Home of the Brave, the doctor, if he lives, is lucky if he gets his bill settled without a discount; if he dies, he gets a decent interment, a notice in a medical journal, and a set of resolutions from his medical society.

ENFORCEMENT OF THE MEDICAL LAW.

It is stated in the *Buffalo Medical and Surgical Journal* that the Erie County Medical Society is determined to prove that the Medical Law is something more than a dead letter upon the statute-book. Many practitioners have failed to register, as the law requires, and the society, in its corporate capacity, propose to inquire into the matter. Other societies in the State have had their attention directed to the necessity of doing likewise. It appears to us that the time has come for some action one way or the other. A good way to make a beginning is to publish a list of registered practitioners. We offer this as a hint to the Medical Society of the County of New York.

THE PREVALENCE OF LEPROSY IN THE UNITED STATES.

At the meeting of the Academy of Medicine, on January 20th, Dr. H. G. Piffard read a paper on leprosy. In this paper and in the subsequent discussion, some facts of much interest, and perhaps of great importance, were brought out. From the statistics collected by the Dermatological Society, it appears that there are between fifty and a hundred lepers in the United States at present. Moreover, an examination of the tables shows that this number has been constantly increasing every year. In view of these facts the question of the contagiousness of leprosy is a most important one, and it was discussed very carefully by the reader of the paper and other gentlemen present at the meeting referred to. Dr. Piffard was inclined to believe that, though not contagious in the ordinary sense of the word, it might be so through the medium of the blood or secretions, as in the case of syphilis. Furthermore, it was a well-established fact, that when leprosy had once gained a foothold in any community it was very sure to spread in some way. A marked illustration of this was to be seen in the Sandwich Islands. Forty years ago there was no leprosy there; now one-tenth of the inhabitants are lepers. Honolulu, a place once entirely free from leprosy, now has two hundred and fifty cases of the loathsome disease.

This view, that leprosy once established in a place spreads in some way, was agreed to by all the speakers, and there is little doubt that it is the actual fact. In view of it and of the loathsome nature of the malady, we may well inquire whether some steps to limit the increase and to prevent the introduction of leprosy shall not be taken. Only a short time ago a number of Chinese lepers were returned to their native country by the health authorities of San Francisco. It is the Chinese who introduced leprosy into the Sandwich Islands, and who are responsible for its spread in other localities. We are constantly exposed to the infection, therefore, on that side of the country, and we are somewhat exposed also, on the east, from cases in the West Indies. It was suggested, therefore, that the National Government be urged to take some action in the matter, by establishing, perhaps, a lazaretto, where sufferers from leprosy could be isolated and receive proper treatment. As preliminary to this, however, an investigation of the exact extent of the disease in this country was very properly authorized, a committee being appointed for the purpose.

The danger of any extensive prevalence of leprosy in this country, where the food and the general hygienic conditions of the inhabitants are so superior, is not very great. Still, leprosy can spread here, and may, in some particular localities, do so with considerable rapidity. The disease is so horrible a one that every contingency should be guarded against.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 20, 1881.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE paper of the evening was read by DR. H. G. PIFFARD, the subject being

LEPROSY,

with a presentation of cases.

The speaker first gave a brief history of the disease. Leprosy is a constitutional affection which shows itself in three different forms: the macular, tubercular, and anæsthetic. These are usually associated together, more or less, but one or the other predominates.

The disease has usually a prodromal stage, which may last for years without causing any very marked symptoms. In time, however, certain reddish brown maculæ, which are hyperæsthetic at first, but are not elevated, appear. The hyperæsthesia is gradually replaced by anæsthesia. Tubercles soon develop along with the maculæ. The favorite seat of these is on the face, but they may appear on other parts of the body, especially the forearms and legs.

These tubercles are hard, elevated portions of the skin. They may eventually ulcerate or remain unchanged, or even disappear in part. The chief cutaneous lesions are bullæ, which may rupture, and leave sores. The extremities are especially affected; here ulcerations may develop, and the hands or feet drop off. The prognosis is unfavorable, though there are probably some cases that have been cured.

The immediate causes are not known. Hygienic and climatic influences do not seem to be the cause, for the disease exists in Norway and Iceland, as well as in the tropics.

The question of the

CONTAGIOUSNESS OF LEPROSY

is one of the greatest importance. In the opinion of East Indian medical officers contained in a report on leprosy, published in 1867, the disease is not contagious. Further negative evidence is given by the fact that for several years, from 1864 to 1869, there was a leper patient in Bellevue Hospital; and during a portion of this time another leper was connected with the hospital in the capacity of nurse. And yet, during that time and since, there has never been a case of leprosy developed in this city. None of the cases observed here were residents of New York at the time referred to above, and none of them ever had any communication with the lepers at Bellevue. On the other hand, it is a well established fact that when leprosy has once gained for itself a foothold in any locality it is apt to remain there and spread. A recent writer, Dr. Bross, a Jesuit missionary attached to the lazaretto at Trinidad, takes the ground very strongly that the disease in some way or other is transmissible. He has written a work of considerable size in defence of this position.

A review of the evidence bearing on the contagiousness of leprosy led the speaker to the conclusion that this disease, like syphilis, is not contagious by ordinary contact, but it may be transmitted by the blood and secretions. Vaccination may transmit it. A case in the speaker's own experience was cited in proof of this.

The subject of the treatment of leprosy involved, first, the consideration of the

PROPHYLAXIS OF THE DISEASE.

The principles which underlie this are well understood. If a community is to be protected from the spread of leprosy, all cases that exist in it should be absolutely separated from the inhabitants, and each new case should be sent to live at a lazaretto with the others. To do this thing, however, always requires the help of the General Government. There are now in the United States over fifty lepers. A suitable lazarette ought to be established, where these cases and all subsequent ones may be isolated and properly treated. National legislation would be required for this. The case of the Sandwich Islands illustrates the danger which a country may be subjected to from the spread of leprosy. Forty years ago the disease did not exist there. Now one-tenth of the inhabitants are lepers.

In the treatment of individual cases, general hygienic measures demand the first attention.

As regards curative treatment, there are some few cases reported which seem to have been cured. In many cases, undoubtedly, the symptoms of the disease are greatly ameliorated, and its progress is retarded. It is not right, therefore, to say that every case is hopeless. The principal indications for treatment are: first, to relieve the pains, to restore sensibility to the anæsthetic parts, and to cause the tubercles to disappear; and, second, to retard the progress of the disease. To fulfil these indications a number of drugs have been employed.

The speaker mentioned a large number of these drugs, and described the results which had been obtained from their use. Among them was the *calotropis gigantea*, a remedy in high repute in India fifty years ago, and still used there. It is considered very efficacious in lupus also. The *hydrocotyle asiatica* was accidentally discovered to be useful in leprosy by Dr. Boileau, who was himself a leper. It still has a reputation for efficacy, but is not a specific. It is used on the island of Mauritius.

The *anacardium occidentale* and bichloride of mercury are used together, salt meat and salt fish being excluded from the diet. In this connection it was stated that nearly every writer insisted upon the importance of including fresh meat in the diet, excluding all salt meats and salt fish.

Lepers are subject at times to a peculiar fever, for which quinine may be given. This fever is especially apt to appear in the later stages, when carious processes set up in the bones.

An oil known as cardol is used with benefit. It is an extremely irritating substance, and is applied externally to the tubercles.

Somewhat similar in action to this is nitrate of silver, strong solutions of which are painted on the parts.

Gurjun balsam has some repute in leprosy.

CHAULMOOGRA OIL

is another drug which has efficacious properties. A number of persons have recommended it, and some cases are reported cured by it. There is now a case at Charity Hospital, under the care of Dr. Sturgis, which has received marked benefit from this remedy. It is given internally in doses of ℥v., increasing to ℥xx. t. i. d. The taste is extremely nauseous, and large doses irritate the stomach. It may be applied externally also.

Nux vomica, in the form of the crude nut, is used in the East, and there asserted to have remedial virtues. It must be taken for a long time.

Hoang-nan is another drug lately come into repute. It comes in the shape of a brownish yellow powder, of intensely bitter taste. It has a tetanizing effect, and probably belongs to the strychnos family. In a letter from a gentleman in Honolulu, where this drug has been tried, it is stated that sometimes the drug did good, sometimes it did harm, and sometimes it had no effect.

Galen recommended the wine in which vipers had been drowned. Following him, perhaps, the homœopaths recommend *lachesis*, which is the venom of a South American snake.

The speaker gave a full account of the treatment recommended by Dr. Erasmus Wilson.

Having concluded his review of the treatment, Dr. Piffard said that, as a result of personal experience, he has found the pains controlled by blisters; the tubercles are lessened under frequent painting with iodine. Chloride of barium internally has produced some improvement; but very decided benefit has resulted from the use of Chaulmoogra oil.

The speaker thought that there would yet be discovered some means of curing leprosy. Heretofore treatment had been entirely empirical. Attempts at a rational treatment, based on a knowledge of the pathology of the disease, had yet to be tried. Dr. Piffard was of opinion that leprosy was primarily a

DISEASE OF THE NERVOUS SYSTEM,

and especially of the spinal cord. The first changes appear to be subacute and inflammatory. These are succeeded by sclerosis, the neuralgia becoming largely increased in amount. This theory is founded upon clinical study and post-mortem examination. If it is correct, it follows that in the earlier stages treatment should be directed to the hyperæmia; ergot, counter-irritation, etc., being given. Later, chloride of barium and mercury; and still later, phosphorus, phosphoric acid, strychnia, etc., would be indicated.

This hopeful view of the prospect of curing leprosy is shared in by other writers, as was shown by several quotations made by the speaker.

The paper being concluded, Dr. Piffard exhibited

TWO CASES OF LEPROSY.

One was that of a man aged sixty-eight years, a German by birth, who contracted the disease in Mexico eighteen years before. He came to this country to live four or five years before the disease appeared. He entered Charity Hospital more than a year ago, and had been under the care of Drs. Sturgis and Piffard since that time. No benefit appeared from any medicines that were given until Dr. Sturgis placed him upon Chaulmoogra oil, externally and internally, when improvement began and is now very great. After taking the oil, the tubercles subsided; the extremities, which before had been almost completely anæsthetic, regained their sensibility. The patient, who could hardly lift his feet from the floor, now walks with ease, and can raise his limbs without difficulty. In response to a question by the President, the patient expressed, with great fervor, his conviction of a wonderful improvement. At one time the oil had to be discontinued; there was then some return of the anæsthesia.

The second case was that of a young man who came from Bermuda two or three years ago. He came to this country, where the disease developed. The patient showed dark macular and tubercles upon the arms and face, and had areas of anæsthesia upon the skin. He had been placed on hoang-nan. Some improvement had followed.

Dr. Piffard, in concluding the subject, said that he hoped to interest the Academy in the matter of ascertaining the number of lepers in the country, and of obtaining from the Government help in isolating them and preventing any spread of the disease; for it was known that when the disease once got a foothold, it would almost certainly spread in some way.

Leprosy is very prevalent in China, and only a short time ago a number of lepers were sent back from San Francisco to their native land. He believed it for the interest of the country that something should be done in the matter.

The paper being open for discussion,

Dr. Sturgis said that the question of treatment had been so thoroughly gone over that he could add but little. In regard to the case which had been taking Chaulmoogra oil, he said that the amount given had at first been ℥v., t. i. d.; but this seemed to produce no effect. The dose was then doubled, and the patient is now taking ℥xx., t. i. d. The oil was applied externally, at first mixed with seventy-five per cent. of vaseline, but now it is applied in the pure form. The improvement produced is very great; whether it is permanent remains to be seen; but it is noticeable that even when from necessity the oil was stopped, the anæsthesia, though it returned, was not so severe, while the tubercles did not enlarge again.

The speaker then referred to the danger which the country was exposed to on both sides from the dis-

ease, as it might be imported from the West Indies, and from China and the Sandwich Islands. There is very little question that the Chinese are responsible for a great deal of the disease. It is stated that Chinese emigrants having the disease brought it to Honolulu, that island being then free from leprosy entirely. Ten years later the disease had spread so much that 250 persons were affected by it. These facts were given in a report made to the Secretary of the Navy in 1869. Leprosy was not known in the Sandwich Islands until Chinese emigration reached there. The disease exists in many parts of China, but it seems to be more prevalent in the marine ports than in the inland cities of the Empire.

There seems to be very little doubt that the question of contagion has a very fair showing. Danielson particularly claims that the disease is contagious, and that it is hereditary, though this point is far from being proved. It may turn out that the disease is contagious only in the earlier stages. At any rate, it is a question that would bear much more investigation than it has yet received, particularly in view of the fact that we are exposed to an increase of the disease.

The question of diet undoubtedly influences the disease. As to how much it has to do with the etiology, the speaker was unable to say. A great deal has been ascribed to the influence of putrid meat, both of animals and fish. Especial stress has been laid upon this point by Norwegian writers.

Dr. T. R. Pooley said that he thought he could add something to the clinical aspects of the disease, as it affected the eye. A work upon this subject had recently been written by Drs. Bull and Hansen. It was shown that leprosy, in a certain proportion of cases, attacked the eye and affected both its external and internal parts, as well as its appendages. Dr. Pooley gave a brief description of the various changes which the disease produced in this organ.

Dr. L. D. Bulkley said that he could add to the descriptions, in the way of several personal cases that he had had. He had treated nine cases of leprosy in its different forms; four of these, however, had been seen, or been under the care more or less of the other gentlemen who had spoken. These cases were of various character. One was of the destructive form, and was affected as badly as any ever described. He had had two patients in his personal care, both of whom were natives of America, both lived in New York, and neither had ever been five hundred miles from this city, neither of them had had any hereditary history of leprosy or any personal relations whatever with the disease.

The first case was that of a man, thirty-eight years old, who lived in Hudson, and who had had leprosy for eight years when he first came to the speaker for treatment. He had the tubercular form in a very characteristic way. The case was studied with great care by a number of gentlemen merely to verify the diagnosis. Dr. Bull, of Norway, was among those who assisted in this. The patient died in the ninth year of his leprosy.

The other case, which was developed in this country, was that of a young man thirty years of age, of healthy parents. He had never been out of the country, had never been 300 miles from New York. The leprosy was of the macular form. The diagnosis in this case was also verified by the Dermatological Society. He died two or three years later, and in about the eighth year of his leprosy. No post-mortem was made.

The question of contagiousness, in the ordinary sense of the term, is pretty well decided negatively. Still, when a book of 300 pages is written in an effort to prove this contagiousness, and by a man who has seen and studied leprosy a great deal, it seems to be very strong evidence that the disease is contagious in some way or other. The speaker would throw his influence, therefore, toward having the question more thoroughly investigated, and for having the Government do something toward stamping it out. The Dermatological Society had adopted a plan of making a census of cutaneous diseases, and every year new cases of leprosy were added to the list. This list, however, is necessarily imperfect, and there is no doubt that the real number of cases is greater than is supposed.

In regard to treatment Dr. Bulkley said that his cases were not submitted to Chaulmoogra oil or to hoang-nan, and nothing that was given them seemed to do very much good.

Dr. Geo. H. Fox said that he was very glad to testify to the marked improvement that had taken place in the patients presented by Dr. Piffard. The improvement was more surprising, inasmuch as the tubercular form of leprosy which these cases presented was considered more obstinate than the anæsthetic form; some observers had claimed that the average life of the former is only about nine years. The speaker said that leprosy was the most terrible disease that afflicts the human system, yet it seemed to be a fact that during the past ten or twenty years the number of lepers in this country had increased; it seemed, also, to be true that where it has once obtained a foothold it is very liable to spread. Here in New York we are apt to find cases of leprosy in our midst at almost any time. Very many sailors are liable to develop the disease.

As to its contagiousness, if there is only a possibility or probability of this, it is the duty of the profession to the community to take whatever measures are in its power to prevent any possible spread of the disease. The physician in his individual capacity can do very little, and some concerted action, therefore, ought to be taken by the profession to learn more about the disease, to prevent its spread, and to ameliorate the condition of the lepers themselves.

Dr. Maxwell said that he had assisted in making the post-mortem on the case of leprosy which had died in Charity Hospital under Dr. Piffard's charge.

The most noticeable changes were in the spinal cord. This showed very marked sclerosis, particularly, as he remembered, in the cervical and lower dorsal regions. The sclerosis appears to affect the whole thickness of the cord. The appearances in other internal organs showed nothing characteristic.

Dr. W. J. Morton said that he had visited lazarettos in South Africa, and that one in particular he had examined with much interest. The physician in charge was an Englishman and a very intelligent man. He had about thirty patients, with about ten children who presented no signs of leprosy. The physician in charge did not think the disease contagious, but the children were believed to be doomed. Still marriage was allowed, and each of the men had stout, healthy wives who did not seem to have any fear of the disease. It was generally believed to be dangerous, however, to marry the widow of a leper. The treatment here was by strychnine, and the doctor in charge showed two cases which were believed to have been cured by the remedy.

Dr. Morton referred to a case seen by him last summer at the clinic of Professor Charcot. The disease had existed for six years, and large patches of

the skin were affected. The treatment was by static electricity, under which the anæsthesia had disappeared and the tubercles lessened in size. One interesting feature of this case was the muscular atrophy which had taken place under the affected skin. Many muscles also showed the reaction of degeneration. All these symptoms had a bearing on the question whether the disease is a nervous one or not.

The speaker referred to certain discoveries, recently announced, of bacteria in the tubercles of leprosy.

Dr. Piffard, in closing the discussion, referred to Dr. Morton's remarks as confirming his idea that the disease was of neurotic origin. The use and value of electricity pointed in the same direction. It had been used by several physicians, as stated in his paper. The discovery of bacteria he had not referred to, because he had not been able to get the original papers on the subject, and he disliked to base anything on abstracts. He did not consider it at all likely that bacteria had anything to do with the causation or progress of the disease.

The case of leprosy whose autopsy had been referred to by Dr. Maxwell, died suddenly of a multiple thrombosis of the lungs.

The discussion being closed, Dr. Sturgis offered the following resolution, which was adopted:

Resolved, That a committee of three be appointed by the President to investigate the extent to which leprosy prevails in this country.

The President appointed Dr. H. G. Piffard, Dr. F. R. Sturgis, and Dr. G. H. Fox.

The society then adjourned.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 28, 1880.

Dr. H. B. Sands, President, in the Chair.

FRACTURE OF THE SKULL, WITH RECOVERY.

Dr. L. A. Stimson presented a male patient with the following history: He was seventeen years old; and, two months ago, while standing near another man who was engaged in "throwing the hammer"—a sledge-hammer weighing eighteen pounds, and attached to a long handle—was struck upon the forehead by the hammer, after it had been thrown. He was brought to the hospital at once, and Dr. Stimson found a scalp-wound over the left frontal tuberosity, that divided all the soft parts down to the pericranium, which was raised by the blood pouring out beneath it, and there was a considerable area of depression. On cutting through the pericranium the bone was found denuded over a space two inches in diameter. That area represented a crater-like depression in which the bone was continuous throughout, and the elevator could not be introduced. He therefore used a small trephine at the border of the depression, and, after removing the button of bone, raised as much as could be raised of the outer table, removed a small piece of the inner table, and finally applied the trephine a second time in order to complete the elevation of the fragments. The wound was treated antiseptically. The incision in the pericranium was closed with catgut suture. The case progressed to a favorable termination without accident. The wound remained open and suppurated at one point for six weeks, and a probe introduced there followed a track half an inch in length, and then touched bare bone. That track, however, finally healed, and the scar was complete, and had been so for three weeks.

One interesting point in the case was that a very considerable amount of bone was left bare and partially separated from adjoining bone, and yet gave rise to no complication.

ABSCESS OF THE BRAIN—TREPHINING.

Dr. Stimson also narrated the following case: A man, aged thirty years, was struck, last spring, upon the side of the head with a stone. He was taken to St. Vincent's Hospital, where the wound was enlarged and the bone was thoroughly examined for fracture or fissure, but none was found. He remained in the hospital a few days, and was then dismissed and treated subsequently as an out-patient. He suffered from headache, and had slight trouble with some of the muscles of his left forearm. After about six weeks he was sent to the medical side in Bellevue Hospital, where he was treated for some time for pachymeningitis. The wound upon the side of his head had entirely healed, leaving a firm non-adherent scar. An informal consultation was held, and opinion was divided as to the exact condition which existed, but all agreed concerning the impropriety of surgical interference. He was then transferred to the surgical side, when he came under Dr. Stimson's care. The patient had no rise of temperature, except, occasionally, a slight elevation, lasting only for a short time, and most of the time he was dull, and sometimes in a condition of hebetude. Within a few days he aroused, and Dr. Stimson, then noticing the scar, asked him to hold out his left arm, when it was noticed that there was paralysis of the extensors of the forearm. The scar was upon the right side of the patient's head, beginning a little behind the upper part of the ear, and extending upward and slightly forward about two inches. Its upper extremity reached to the so-called motor area, and to a point which corresponds to the supposed area of motion for the hand and forearm. He thought the circumstances were such as justified an operation, and called a consultation, which was attended by one gentleman who agreed as to the propriety of an operation. The patient had again become stupid, and was so unconscious that an anæsthetic was not required. Dr. Stimson made a crucial incision at the upper end of the scar, and as soon as it extended through the skin a loose piece of bone was struck. Upon working down to it, he found a piece, half an inch long, of the outer table alone, and as thick as a piece of thick blotting-paper, and about one-sixteenth of an inch wide, lying in a groove in the bone, but not surrounded by any pus. After removing this piece, he felt a small opening which extended through the bone. The trephine was then applied to the edge of the opening, and upon removing the disk the dura mater was exposed and found to be thickened, covered with granulations, and not pulsating. He then introduced a hypodermic needle a quarter of an inch, did not obtain any fluid, introduced it a quarter of an inch deeper and obtained pus, and then passing a knife in, evacuated two ounces of pus. A probe was then introduced, entered a cavity, and encountered a firm wall. The wound was dressed antiseptically. The patient did not recover his consciousness, and died nine hours afterward. At autopsy the abscess was found so reduced that the cavity was not larger than a small pea, and its location corresponded very closely to the area mapped out by physiologists as the motor centre for the hand and forearm, namely, just behind the middle portion

of the right ascending parietal convolution. There was no fracture of the bone. The original injury seemed to have set up osteitis, which caused exfoliation of a portion of the outer table, and the abscess in the brain seemed to be one by proximity.

Dr. Sabine thought that the case seemed to show that the limits accorded to this motor region had been made too exact by physiologists. Certainly an abscess which contained two ounces of pus would not only encroach upon more than one convolution, but would probably produce outside changes, and the man should have had more than paralysis of the extensors.

Dr. Markoe remarked that the interest in the case, so far as localization was concerned, was the fact that within two weeks, probably, after the receipt of the injury, the defective movements of the muscles were manifested. The abscess probably encroached upon other regions, and doubtless produced other signs, which in turn were masked by the coma produced by the abscess itself.

Dr. Lange suggested that the formation of the abscess was so slow that the surrounding centres became accustomed to the pressure which it produced, and therefore gave rise to no symptoms.

Dr. Stimson regarded it as a reasonable supposition that the abscess had formed at the expense of a limited amount of the cortical substance of the brain, and that other portions of the brain had adjusted themselves to this pressure.

DISLOCATION OF THE OUTER EXTREMITY OF THE CLAVICLE WITH FRACTURE OF THE ACROMION PROCESS.

Dr. T. T. Sabine narrated a case which he had in St. Luke's Hospital. A woman, very stout, and fifty years old, was thrown down and trampled upon by a horse. She was clear and positive in her statement that one of the horse's hoofs struck and pressed upon the front part of her right shoulder. The patient was anæsthetized, and, after careful examination, Dr. Sabine made out very distinctly—also satisfactory to three members of the house staff—that there was dislocation of the acromial extremity of the right clavicle, which was thrown upward and backward, and, in addition, fracture of the entire acromion process. The injury had probably been produced by the pressure of the horse's hoof, first causing dislocation of the clavicle, and, second, the pressure continuing, the acromion had separated at its narrowest part. There was no crepitus, because the broken surfaces could not be sufficiently approximated to produce it. There was no evidence of contusion of the skin.

PERITYPHLITIC ABSCESS—FÆCAL CONCRETION.

The President presented a fæcal concretion, which he had removed from a perityphlitic abscess he had opened, in the usual manner, six days previously. It had shrunken somewhat since its removal, but even then was more than half an inch in one diameter and three-eighths of an inch in another. There was no fluctuation at the time of the operation. After matter, in considerable quantity, had been allowed to escape, and no foreign body was detected, Dr. Sands explored the cavity with the index-finger, and discovered at several inches from the opening a concretion, which he hooked out with the finger. If the finger had not been used in exploration the concretion might have remained at the bottom of the cavity for an indefinite period.

The President also referred to a case which occurred several years ago, and in which a concretion, not more than half the size of the one presented, was retained after the abscess had been opened, and caused a recurrence of the disease after the patient had apparently recovered and left the hospital.

In the case from which the specimen presented was obtained, Dr. Sands noticed particularly that, when the abscess was opened, no gas escaped. He regarded it as somewhat remarkable that in these cases of perityphlitis, due to intestinal perforation, fecal fistula was not established. Before the disease culminates in abscess the concretion escapes and the opening becomes plugged. He thought that this fact was in accordance with the teaching of pathological anatomy; that in these cases perforation occurs of the appendix vermiformis and not of the caput coli, although perforations of the cæcum do sometimes take place and give rise to such abscesses. But if perforations of the cæcum were the rule instead of the exception, fecal fistula would doubtless be more likely to result than where perforation takes place of the long and slender appendix.

In the present case there was nothing to indicate the existence of suppuration except continued high temperature. There were not, at any time, severe symptoms of peritonitis. The signs of local inflammation were well marked, but they subsided under the use of leeches, fomentations and opium, and the pulse fell to nearly its normal standard, yet the temperature remained high. On the fourteenth day, when the operation was performed, the temperature was 103° F. It was the continued high temperature that led to the use of the exploring-needle, when pus was detected. There was no localized œdema, and no recognizable tumor, but some tenderness over the seat of abscess.

Dr. Markoe referred to a case in which a fecal fistula remained for a long time.

Dr. Sabine referred to a case in which he removed a fecal concretion, between two and three months after the abscess had broken, which prevented the abscess from closing. In that case the fistula was clearly beneath Poupart's ligament. Probably it was not originally so, as there was very extensive undermining of the skin when the case first came under his care.

The society then proceeded to the transaction of miscellaneous business.

THE NEW YORK SOCIETY OF GERMAN PHYSICIANS.

Stated Meeting, December 17, 1880.

Dr. H. Knapp, President, in the Chair.

Dr. Seibert read his report on atrophy of the heart in conjunction with fatty deposit beneath the pericardium.

HEMORRHAGIC INFARCTION OF UPPER EYELID.

Dr. Knapp presented a male patient, the subject of an ocular affection, which, strictly speaking, did not constitute a disease in itself. The case was one of embolic infarction in the upper eyelid, and the patient had given the following history: About three weeks ago he awoke one morning to find a painless, œdematous infiltration of the upper lid and conjunctiva. Eight days later he came to Knapp's clinic, when his conjunctiva was found to be injected and in a condition of chemosis. There was no discharge, nor did the bulbus show any abnormal condition. On everting the lid, a rounded induration, mottled with

black spots, appeared in the lid. It was about three lines in diameter, showed some central softening, and was surrounded by an area of infiltration. The conjunctival covering of this consolidated portion was not destroyed. The absence of ulceration, together with the presence of central softening, as well as the denial by the patient of traumatism or infection, justified the exclusion of injury or chancroid from the list of possible causes. Cleanliness was the only suggestion of treatment. On the following day the central softening was found to have extended, and twenty-four hours later, capillary hemorrhagic spots were discovered at the lower border of the induration. At this time the above diagnosis was made. The case progressed favorably, and at present absorption was going on without any indication of existing necrosis.

The distribution of the terminal arteries in this locality was not such as to favor embolic processes, hence similar observations had not been frequently made. Nor would he be inclined to attach any special value to the present case, were it not his opinion that similar processes of connective-tissue infiltration had been described, and were known as essential œdema of the lids.

In this connection he also showed a specimen, accompanied by a drawing illustrating a case of embolic infarction of the retina, first seen by himself a number of years ago.

Dr. Kucher alluded to the well-known case of General Radetzky, where enucleation of the eyeball was seriously contemplated for supposed orbital tumor, but when under expectant treatment both œdema and exophthalmus entirely disappeared.

Dr. Jacobi asked if the present case was not rather to be regarded as one of thrombosis, such as is encountered elsewhere in the body. The patient presented had no cardiac lesion, a fact which gave this supposition additional weight.

Dr. Knapp replied that the wedge-shaped form of the consolidated tissue, taken in conjunction with the occurrence of capillary hemorrhages, militated against the interpretation of the phenomena as due to thrombosis. Moreover, thrombosis in this region commonly spread to the sinus cavernosus, and was accompanied by febrile manifestations, neither of which was found here.

Dr. Gruening also thought the case under discussion might be one of thrombosis. Michel and Hutchison had recorded examples of sudden thrombosis of the central vein, unaccompanied by fever.

OVARIAN CYST, WITH FATTY DEPOSIT.

Dr. Garrigues exhibited the above specimen, which had been previously presented at a meeting of the Pathological Society. (See Medical Record, January 1, 1881.)

Dr. Jacobi observed that the diverticulum found in the cyst-wall might be explained by early fetal inclusion.

ANGIO-SARCOMA OF EYELID AND TEMPLE.

Dr. Jacobi presented specimens of this variety of neoplasm. The tumors had been removed from an infant born February 4, 1880, on the day following its birth. These congenital growths were supposed to be angio-lipomata, until a microscopical examination demonstrated their sarcomatous nature. An interesting structural peculiarity of the tumors was their richness as regarded lymphatics.

Dr. Kucher referred to a diffuse infiltration of similar structure covering the thorax of a child, and not amenable to surgical interference.

PRIMARY RENAL CANCER—PERINEPHRITIC ABSCESS.

Dr. Jacobi presented a specimen of primary carcinoma of the kidney, which during life had simulated pyonephrosis, the patient having been treated on the diagnosis of the latter condition. The history, briefly summarized, was as follows: The patient, aged fifty-three years, had been ailing for several years, during which time he had suffered from various urinary troubles, which often took on the character of renal colic. Nevertheless, there existed neither urethral stricture, nor had concretions ever been passed with his urine. In February the appearance of pus in the urine led to the diagnosis of pyelitis. In May he went to Europe, spending the summer in the south of France. There he was not improved, and, utterly prostrated, he once more returned to this country, though he did not expect to survive the ocean trip. Shortly after his arrival here, on the 22d of September, he was seen by Dr. Jacobi. He found him suffering with air-hunger (*lufthunger*), and having a temperature of 103° F. At the left upper portion of his thorax there was dulness on percussion, and extensive râles were heard. It was thought possible that multiple pulmonary abscesses existed, but the patient rapidly improving, this supposition was abandoned. The urine contained a considerable proportion of pus. The region of the left kidney was distinctly tumefied, and quite tender to the touch.

A week later pus was here found by means of the aspirator. Accordingly the abscess was incised, much purulent matter evacuated, and a drainage-tube inserted into the wound. The cavity was washed out alternately with solutions of thymol and carbolic acid. Little benefit accrued to the patient from these measures. Rigors were still at times observed. The pulse often ranged from 120 to 130. A distressing cough continued to weaken him, the cause of the cough being a chronic naso-pharyngeal catarrh. The urine, however, gradually became clearer, showing less slime and pus; the cavity of the abscess diminished in size, and now only admitted one and a half ounces of fluid. But the appetite became persistently poor; he began to sink rapidly. When, at length, a lobar pneumonia developed, together with erysipelatous inflammation around the wound, the patient died.

At the autopsy, instead of finding the diagnosticated pyonephrosis, a perinephritic abscess was discovered. The purulent collection was in contact with the kidney at its posterior aspect, and the organ itself was considerably augmented in volume from cancerous deposit. The other kidney was also the seat of carcinomatous invasion, but to a less extent. On the liver some small secondary nodules were found. The omentum showed numerous large deposits of the neoplasm.

TRACHEAL TAMPON-CANULA.

Dr. Gerster demonstrated the mechanism and mode of application of a new canula of this kind, which had been made according to his directions by Tiemann. It was claimed for this new instrument that, unlike a similar apparatus constructed by Trendelenburg, when once secured within the trachea it would be perfectly and permanently reliable. In place of Trendelenburg's inflatable membrane, this instrument contained a contrivance resembling the collection of strips of steel used in Otis's ure-

thrameter. By means of a suitable screw the calibre of the canula could be increased until the trachea would be completely closed. The dilatable portion of the instrument, corresponding to the adjusted steel strips, was provided with a covering of thin rubber. Experiments on human corpses had proved the perfect action of the apparatus, which was more solidly constructed than Trendelenburg's canula. The inconveniences and accidents attending the use of the latter instrument were thus entirely obviated. As regarded that portion of the canula which subserved purposes of inhalation, it was made after a similar adjustment of Trendelenburg's instrument.

Correspondence.

PERSONAL EXPERIMENTS WITH THE INHALATION OF SULPHURIC ETHER.

To the Editor of The Medical Record.

Sir—Reading the report of the "Committee on Anæsthetics," appointed by the British Medical Association, has induced me to publish the result of some experiments, made by myself eight years since, on the physiological effects of ether as an anæsthetic, and also my experience of it in the same capacity during the last ten years. When I was an interne of Bellevue Hospital, during 1869–70, and saw ether administered, I used it myself in a large number of cases without having occasion to be alarmed at any of the symptoms produced by it, or having to wait more than five minutes for an effect sufficient for any operative procedure. Since then I have constantly used it with the same results, having never seen anything approaching a fatal case, nor failed to produce complete anæsthesia. In 1872 I inhaled ether myself for the purpose of experiencing in my own person its physiological effects and noting the amount of anæsthesia produced, and also the amount of rational consciousness remaining while insensibility to pain continued. My experiments resulted in a perfect demonstration to my own mind of the following propositions:

First.—Ether affects the *terminal ramifications* of the nerves *first*.

Second.—That complete insensibility to pain may be produced by ether, while entire rational consciousness remains. Thus, while perfectly conscious of everything, I could stick a pin or make a small incision in any part of my body without feeling any pain whatever. I also noticed that the peculiar deadness or numbness began in the feet and hands first, and extended gradually to the trunk, until—although fully conscious *mentally*—I did not know that I was breathing unless I *looked* at my chest and *saw* it rise and fall. Finally, I was only aware of the cool feeling produced on the tip of my nose by the passage in of the air, and then complete oblivion, lasting, however, only half a minute. I had my watch in my lap and noted the time from my last recollection to my first awakening, for, of course, the handkerchief containing the ether fell from my hand during unconsciousness, and destroyed the continuous effect of the anæsthetic.

Third.—Ether mixed with *much atmospheric air* can be inhaled for hours without producing unconsciousness—sufficient for the quiet performance of a delicate surgical operation. Although sensibility to pain may be abolished during the whole time, yet reflex movements will occur on the application of a sharp stimulus.

Fourth.—That ether almost *undiluted* with air, after the few free respirations, produces rapid anæsthesia and *mental unconsciousness* with complete muscular relaxation, amply sufficient for the uninterrupted performance of any capital operation.

Fifth.—That the condition above-mentioned, being once produced, can be easily maintained for hours by slight additions of ether diluted with air.

Sixth.—That ether *increases* the blood-pressure, and that it enfeebles the pulse only after long-continued and excessive administration. That it gradually produces an increasing slowness and shallowness of respiration, and that in my opinion it kills only in this way, and that if the heart should become enfeebled it is a secondary result of the pulmonary lethargy.

In conclusion, I would say that I have seen great benefit result from the moderate inhalation of ether where cavities existed in the lung; that I have given it to patients afflicted with nearly every form of disease, without having occasion to be dissatisfied with its action as an anæsthetic or alarmed at its operation as a narcotic. I believe that the trouble in producing anæsthesia with ether, complained of by some surgeons, is due to the fact that they are afraid to administer it *undiluted* with air. *I* always use Lente's improved inhaler—an impervious brass nose-piece with rubber stuffing on the edge to make it air-tight. I have always given ether *undiluted*, with the exception of a few inhalations at first to accustom the air-passages to the vapor. Given in this way, I believe it is perfectly safe and efficient. The fearful mortality of chloroform speaks for itself in the report of the eminent men referred to above, and it would be needless for me to discuss the question. Ethidene is only spoken of as *less* dangerous than chloroform; but why use an anæsthetic that is dangerous *at all*, when ether is as safe as anything of the kind can ever be, solely for the purpose of saving a few minutes' time. Chloroform is tricky and uncertain. Ether can only kill, in my opinion, by stopping the respiration, which can be easily watched and the administration controlled to suit any emergency. The few deaths recorded against ether represent so small a percentage as to be almost infinitesimal, while you cannot read a journal without noting one or more deaths from chloroform.

I have performed and seen others perform operations lasting one and one-half hour, under ether, without the slightest consciousness or reflex movement intervening to interfere, and without an alarming symptom, even in delicate patients. Indeed, my experience with ether is that women and children are *most* calmly and easily brought under its influence, and robust, muscular men least; although these latter can always be anæsthetized by a minute or two of undiluted ether. I would feel uneasy only at giving it in a case of kidney disease when uræmia was imminent.

As to mixtures of ether, chloroform, alcohol, etc., I consider them as of no use, because the different specific gravity of the vapors of these substances will cause them to be inhaled *separately*, however well they may be mixed. I merely state these results of my own experience, hoping they will be of benefit to the profession; but I do so without going into the details of the experiments which led me to adopt these views—that would be tiresome. Let each one prove it for himself, if he disbelieves. As to chloroform, it is almost criminal to use it to save a few minutes' time,

when we have a perfectly safe substitute in ether. I wrote this off just as it came into my mind, so that any shortcomings, I hope, will be excused.

BLAIR D. TAYLOR,
Capt. and Asst. Surgeon, U.S.A.

GOVERNOR'S ISLAND, N. Y. H.,

"PLAIN ENGLISH" AND THE METRIC SYSTEM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—I was so intrepid as to offer a few suggestions to those who were inclined to favor the metric system, in an article which appeared in the RECORD of the 8th inst., which article has furnished the inspiration for a somewhat satirical editorial in the *Michigan Medical News* of January 25th, and a "Plain English" communication from Dr. S. P. Hubbard, of Taunton, Mass., in the RECORD of January 29th.

The *News*' editorial is remarkable principally for its prolixity of cheap sarcasm and its absence of ideas.

I cannot refrain from calling the attention of the editorial space-filler of the *News* to a passage (with which he is undoubtedly familiar) from Macaulay's "History of England."*

Referring to the establishment of diligences in England, in 1669, he says: "As usual, many persons were, from mere stupidity and obstinacy, disposed to clamour against the innovation, simply because it was an innovation. . . . . It is not impossible that our descendants, when they read the history of the opposition offered by cupidity and prejudice to the improvements of the nineteenth century, may smile in their turn."

Dr. Hubbard's article is more open to criticism. Referring to the arguments used in favor of the metric system, he says: "This all looks well on paper, but the thing cannot be demonstrated. The absurdity of the system has been shown up by able scientific men, and the greatest of all." Although slightly ambiguous, I think I get his meaning. I have never before heard it objected that the system was absurd, nor that there was anything about it incapable of demonstration. The popular prejudice seems to be that our present system is *good enough*, and that the advantage to be gained is not worth the trouble involved in making the change. Our conception of quantities is in grains, drachms, etc., and it may require the practice of years to forget fifteen grains when we think of the size of a gramme. If the system is better than the other, this is no sufficient objection, and it is an inconvenience that will affect only the generation that effects the change. I believe nearly all who have given thought to the subject will agree that, if the change was completely made, it would be desirable.

The doctor says: "We might as well compel medical men to learn and use the French language as to compel them to use the metric system." This assertion will hardly be convincing to the average reader, as there are no terms required which are not so thoroughly Anglicized as to be found in any English dictionary, medical or otherwise, published within the last half-century.

"This brings (he says) another thought on the writers for medical journals, viz.: it seems as though they were very desirous of showing they had a smattering knowledge of Greek and French, by their compound words made up of a combination of Greek, Latin, French, Spanish, with a sprinkling of Dutch and Indian thrown in."

This is a very withering "thought on the writers for medical journals," and perhaps not entirely unmerited by many; but does not the gentleman's house have at *least* one exposed window? and to one so familiar (by name at least) with languages, this should be a matter of indifference.

His conclusion is one at which, I think, many readers will arrive, and is not altogether illogical. It is as follows: "*A little learning is a dangerous thing.*"

C. H. EAMS, M.D.

EAST SAGINAW, MICH., January 31, 1881.

* Macaulay's History of England. Porter & Coates' ed., p. 345.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR—It seems to me that for a method so very "simple" the metric system requires a good deal of explanation. I have noticed this fact in numerous discussions of the subject appearing in the RECORD since 1876, and the writer has yet to find, in a tolerably thorough study of the subject itself, and of various articles devoted to its discussion, wherein it can be more readily utilized in writing prescriptions than the old way. Besides its manifest inadaptibility to the needs of the practitioner who *is* a *practitioner* and not a *theorizer*, I am opposed to the system upon the one or two general principles involved; one in point is the "international" idea of the matter. As a correspondent in the RECORD said lately, we may as well have an international language in which textbooks shall be printed, and with which every physician worthy the name should familiarize himself, and this because some European druggist may cause harm and disaster through a misapprehension of the meaning of American prescriptions written in the old way! We have been so long accustomed to hear of the excellence of the education, both classical and professional, of European physicians and druggists, that we should consider it a matter of equal indifferance to them whether a prescription were written in English or Sanscrit. A pertinent question is, When shall the medical profession of America become *American* and cease to be imitators of the fashion-plates of Europe? When shall we cease to sink our individuality in following, blindly, transatlantic opinion?

Our country, as a nation, is the foremost in intelligence of population and excellence of government on the earth, conforming to the laws, customs, and manners of no nation but America; is it a fact that the medical profession of the United States is so far behind that it is eagerly grasping at and adopting every innovation that comes across the water. There are a few good souls in the profession, principally upon our eastern coast, for whom it is almost a pity that America was discovered, otherwise they might have been revelling in that atmosphere for which their superior intellectual (?) qualities specially fit them. Conventional Listerism (I am glad of it) is on the wane, and I venture to predict that in another decade those who so enthusiastically advocate the metric system will laugh at themselves to think how silly they were; it will have gone the way of Listerism.

J. B. STAIR, M.D.

SPRING GREEN, WIS., February 3, 1881.

AN INTERNATIONAL SANITARY EXHIBITION is to be held in connection with the International Medical Congress, in London, next year.

New Instruments.

A NEW PROCEDURE IN THE OPERATION FOR PHIMOSIS.

By R. J. LEVIS, M.D.,

SURGEON TO THE PENNSYLVANIA HOSPITAL AND TO THE JEFFERSON COLLEGE HOSPITAL.

The object of the instrument illustrated in the cut is to facilitate the entire excision of the inner inelastic mucous membrane of the prepuce, without removing any, or more than may be required, of the outer, normal skin. In some cases of phimosis total circumcision is necessary, but in a considerable proportion only a partial ablation of preputial integument is essential, and the inconvenience may be readily overcome by the method I suggest, without causing disfigurement, or, indeed, making much change from the normal appearance of the organ. In most instances only the inner lamina of the preputial fold is morbidly involved, and the excessive removal of the outer layer is an error which is liable to be committed in the usual manner of operating.

In general form the instrument somewhat resembles the ordinary mathematical compasses or dividers. The limbs, or blades, terminate in blunt points, and are deeply serrated on their outer surfaces, with points or teeth set backward, like fine saw-teeth, for the purpose of firmly holding the mucous membrane, without the risk of slipping when traction is made. The blades are forced apart by a thumb-screw.

In operating, the blades, closed to a point, are introduced within the prepuce up beyond the corona of the glans. They are then, by turning the thumb-screw, strongly separated, so as to render the mucous membrane tense. Traction is then made, and the outer elastic skin is drawn back fully, so as to be away from the portion to be excised, and excision is effected by transfixing the prepuce through the middle with a bistoury, and cutting laterally in both directions toward the blades of the instrument. Any remaining portions of inelastic tissue may be removed with the scissors, and the operation is completed by attaching the cut edge of skin to the edge of mucous membrane remaining around the cervix by a few stitches. In this manner the inner inelastic mucous membrane may be removed while all the normal outer integument remains.

The instrument may be obtained from any of the prominent surgical instrument makers.

Dr. W. E. Crook, a prominent physician of Alabama, died a few days since in Mobile.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 6, 1881, to February 12, 1881.

Lippincott, H., Capt. and Asst. Surgeon. Upon expiration of present leave of absence, to report in person to Commanding General, Department of the Platte, for assignment to duty. S. O. 34, A. G. O., February 10, 1881.

Girard, J. B., Capt. and Asst. Surgeon. In obedience to S. O. 14, C. S. from A. G. O., relieved from duty in Department of Texas. S. O. 20, Department of Texas, January 29, 1881.

Reed, W., Capt. and Asst. Surgeon. To accompany Battery I, 2d Artillery, from Fort Ontario, N. Y. —abandoned—to Fort McHenry, Md., and then report by letter to these headquarters for further orders. S. O. 25, Department of the East, February 9, 1881.

Gardiner, J. de B. W., Capt. and Asst. Surgeon. Relieved from duty in Department of Arizona, to proceed to Baltimore, Md., and on arrival report by letter to the Surgeon-General. S. O. 34, C. S., A. G. O.

The Medical and Surgical History of the War, and the Proposed Publication of an Extra Edition of Fifty Thousand Copies.—In the last number, and during our temporary absence from the city, an item appeared endorsing the bill before Congress providing for the publication of fifty thousand extra copies of the "Medical and Surgical History of the War." The writing and insertion of the item were due to an inadvertence of a member of the staff who at the time misunderstood the situation of the Record. Hence, while correcting this error, we take another occasion to repeat our former opinion regarding the measure proposed in the bill. There is no necessity for the appropriation. The volumes are not yet so scarce as to warrant the outlay. Members of the profession who really wish the volumes can obtain them at a small price at the old-book stands. Again, the measure is not so much for the benefit of the profession as for the congressmen who have these volumes for distribution; and the major part of the volumes, it is safe to say, will be distributed to non-professional readers, and used as campaign documents. The profession does not desire to be responsible for this large appropriation on any such grounds as are advocated in the bill. We are more emphatic than ever in saying that the passage of the bill would be a useless and shameful waste of the public money.

THE "SIXTY SURGEONS' BILL" is a measure that seems likely to be favorably acted upon by Congress. It provides an increase of facilities for the examination of and adjudication of pension claims. It authorizes the Secretary of the Interior to appoint a pension examiner and a surgeon to each congressional district who shall sit in different parts of the district, according to the convenience of the claimants. In case of necessity the Secretary is authorized to appoint as many as four more district surgeons. He can also appoint special examining boards of surgeons. If the bill becomes a law it will involve the appointment of three or four hundred medical men to these positions.

A VERY BAD MAN.—A student of the University Medical College, and a graduate of two other institutions, was recently arrested in this city for carrying concealed weapons (a small sword-cane). He confessed to having a wife seventeen years old who weighed 244 pounds, and he stated that he did a business in cadavers with outside medical colleges, charging twenty-five dollars apiece for them.

THE THIRD ANNUAL RECEPTION OF THE NEW YORK MICROSCOPICAL SOCIETY was held on Monday evening, February 11th, at the rooms of the New York Academy of Medicine. Mr. Romyn Hitchcock, President of the society, delivered the annual address, his subject being "The Relations of Science to Modern Thought." Exhibitions of objects were made by members of the Society.

THE CAUSES OF DIPHTHERIA.—Dr. A. T. Conley, of Cannon Falls, Minnesota, writes: "I read with interest Dr. J. W. Pinkham's article in the January 22d number of the MEDICAL RECORD, on the cause of diphtheria in the Crump family, of Montclair, N. J., the more so as our State is suffering severely this winter from that dread disease, and our village and surrounding country have just passed through the worst epidemic ever known in these parts.

"After careful study of the disease, I have become convinced that we cannot find the specific cause of diphtheria in the effluvia of decaying vegetable or animal matter, conveyed either through air or water, for this reason: we have had so far a much more than ordinarily severe winter—not a single thaw since the last of October, the mercury most of the time below zero, and yet, perhaps, Minnesota never suffered so severely from diphtheria. I believe medical men will agree with me when I say that the most malignant epidemics of diphtheria are to be found in the Northern States *and in the winter*.

"How can this be accounted for by the advocates of the theory that the specific cause can be found in the decomposition of vegetable or animal matter, when no such decomposition is taking place? Dr. P.'s case would have been much stronger had some of the Crump children slept in rooms not supplied by air from the furnace, and thereby apparently escaped the disease. The fact of *adults* sleeping in such rooms and not taking the disease proves nothing, as all admit that diphtheria is a disease of childhood. Of the 140 cases in our village and vicinity, only three were adults over twenty years of age, and they all recovered. Is it not a fact that hostlers and persons who sleep in barns and livery-stables are a very healthy class, and seldom take diphtheria or other zymotic diseases? and yet the air is always loaded with the kind of effluvia the doctor speaks of.

"There may be such a thing as spontaneous diphtheria, but I think not more likely so than of small-pox. Dr. P. says there have been thirteen fatal cases of diphtheria recorded in Montclair in the last fourteen years. If the Crump family had, under like circumstances, taken small-pox, with the same record of fatal cases in the town, would he have accounted for it in the way he did for the diphtheria, or on the ground of contagion? I believe, for children, diphtheria is as contagious as small-pox.

"As soon as diphtheria appeared in our vicinity, we had a competent sanitary committee appointed, who visited every house, and examined into all sources of filth, and our village was put into the best sanitary condition possible, and yet the disease has carried off twenty-two of our children in the dead of winter. I have further noticed that filthy families have suffered no more than the cleanest, that families who lived in the immediate vicinity of manure-piles suffered no more than those who were far removed from such sources of contamination.

"I believe we have only succeeded in getting rid of the plague by the strictest quarantine, closing all schools and churches, and prohibiting public gatherings of all kinds, and allowing only physicians and nurses to visit the sick; the village paying a man to take orders and deliver everything needed by families where the disease existed, at the gate, and after the disease subsided, thoroughly disinfecting and cleaning up. In short, treat it the same as small-pox. I believe I can trace every case, and account for it by contagion solely, in our village.

"Now, while I am a strict believer in the laws of hygiene, and that cleanliness is next to godliness, and that towns and cities cannot be too strict in enforcing all laws for the removal of all sources of filth, still they must go farther in dealing with diphtheria, and enforce strict quarantine, and the sooner medical men are united on this point the sooner will diphtheria lose much of its formidableness."

TRIPLETS.—Dr. J. M. French, of Simsbury, Conn., reports a case of triplets occurring in his practice. The patient was twenty-seven years of age, and this was her second confinement. The labor progressed normally, each child presenting by the head. The placenta was single with three cords. Altogether the children weighed six pounds, were males, and died soon after birth.

THE DECLINE OF THE BACILLUS.—Dr. A. Jacobi, in his recently published work on diphtheria, takes ground against the germ theory. Buchner and Popper, of Goettingen, have lately shown that anthrax may possibly occur without the *bacillus anthracis*. Dr. Albrecht, of St. Petersburg, has lately announced that in two cases of relapsing fever, a disease which has been considered as certainly caused by a microscopic organism, this organism could not be found, or only in an extremely small number. These facts all seem to point one way toward the decline in the importance of the bacillus.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.—The officers of the Pathological Society of Philadelphia for 1881 are: *President*, Dr. S. W. Gross; *Vice-Presidents*, Dr. W. F. Norris, Dr. James Tyson, Dr. J. Solis Cohen, Dr. F. P. Henry; *Secretary*, Dr. S. F. Hazlehurst; *Recorder*, Dr. C. B. Nancrede; *Treasurer*, Dr. R. G. Curtin; *Curator*, Dr. Carl Seiler.

VISUAL EXALTATION IN TRANCE.—The following experiment in trance-seeing was recently made in this city by three physicians, members of the New York Neurological Society. The subject was a lady, of sensitive, nervous temperament, who for some years

had shown a peculiar susceptibility to the trance condition. There were present at the experiment the three gentlemen referred to, the subject, and her husband, who mesmerized her. After being put into the trance-state, a folded handkerchief was placed over each eye, two other handkerchiefs were then passed around the head and bound over these, making four handkerchiefs in all over the eyes. A leather strap was, in addition, carried over the lower part of the bandage and round the head, so as to hold the handkerchiefs firmly down. One of the experimenters had had his eyes bandaged in the same way, previously, and he could not distinguish light from darkness, even when his eyes were open. The subject's eyes were closed when she was mesmerized, and she stated that she could not open them at all. The bandaging being completed, the subject was placed in a chair, with her back to the light of the window. Her husband was blindfolded and sat at the other end of the room. Some sheets of paper, with blocks of bright color which had been painted that day by one of the physicians, were then produced, and one of them was given to the subject. She took it in her hand, and after a moment, during which her face grew flushed and she appeared in a state of great nervous excitement, she told the colors correctly. A new pack of cards that had also been brought by one of the experimenters, was shuffled and laid upon the table with the backs up. One of these was given to the lady; in a moment she told the color, then the kind, then the number of spots; the queen of diamonds was then handed her, and she told it instantly. Other cards were also told. A card that happened to be in the pocket of one of the gentlemen present was then produced, he alone of the party knowing what was printed on it. This was read correctly. It was "No. 9," the printing being rather large. The visual exaltation seemed to be greater at times; it finally disappeared entirely. A peculiarity noted was that the visual impression occasionally lasted for a few minutes. Thus, a three of diamonds was handed to the subject; after trying some time she failed to see it, and laid it down; a second card was then given her which she declared at first to be the three of diamonds, but afterward read it correctly. Other experiments confirmed the truth of this peculiar feature of the phenomenon. A perfectly opaque body placed before the eyes prevented the reading. It seemed necessary that the luminous rays should at least strike the face. The objects appeared to the person reading very greatly magnified.

The experiment was considered a demonstrative one by those who conducted it. It was similar to those conducted by the French Academy many years ago, when it investigated the subject of mesmerism. The phenomena were then pronounced genuine. On the other hand, an investigation of similar phenomena once made in London, showed that the blindfolded subjects had acquired the trick of working the handkerchiefs down so that they could see up over the top. This, it is said, was not possible in the experiment described above.

Philadelphia County Medical Society.—At the annual election of the Philadelphia County Medical Society the officers for 1881 were elected as follows: *President*, Albert H. Smith; *Vice-Presidents*, H. Y. Evans, Charles K. Mills; *Treasurer*, W. M. Welch; *Recording Secretary*, Henry Leffmann; *Assistant Secretary*, J. D. Nash; *Corresponding Secretary*, John B. Roberts; *Reporting Secretary*, Frank Woodbury.

Trichinosis in Syria.—An alarming epidemic of trichinosis has appeared in a village near Mount Hermon. The inhabitants had nearly all of them eaten the flesh of wild boars that had been killed on the neighboring mountain. Two hundred and forty persons were seized with severe symptoms of the disease. This is said to be the first instance known in which the flesh of wild boars had caused the disease.

Insusceptibility to the Effects of Nitrous Oxide.—Mr. George Lyddon related two cases to the Odontological Society of Great Britain, in which the inhalation of nitrous oxide produced no effect whatever. The first was that of a clergyman, apparently healthy. Twenty gallons were inhaled by him, but with no more effect than if it had been common air. The other patient was a lady, and anæsthesia was subsequently induced by chloroform. No explanation of these anomalous cases could be given. The gas was pure and the apparatus in good order in each instance.

Local Applications of Turpentine in Diphtheria are very highly recommended by Dr. W. W. Cleave in the *Louisville Medical News*. It should be put on with a mop every two or three hours, until every vestige of the membrane disappears. It penetrates the deposit, lifts it off, and leaves a red, shining base, that very soon gets well.

A Case of Polyuria Cured by Ergot is reported by Dr. E. McClellan, U.S.A. (*Louisville Medical News*). The patient, a man aged thirty years, had had diabetes insipidus for many weeks, and passed from ten to twelve quarts of pale, acid urine daily. After quinine had been tried with no success, he was put upon ext. ergot, fl. ʒ ss., q. 4 h. In four weeks he was discharged cured.

Notes on Recent Remedies.—Dr. James Sawyer writes on the above subject to the *Practitioner*. Speaking of *fuchsine* in the treatment of Bright's disease, he says: "I think the fuchsine treatment has given me better results than any other medicinal treatment in renal albuminuria. Fuchsine is an aniline dye, and appears to be mainly excreted with the urine. A patient taking it experiences no inconvenience from its effects. His urine becomes of a rosy pink color, and his fæces are often tinged with the same hue. The drug, to prevent stinging the lips and mouth, should be given in pills, dose, gr. j., t.i.d."

In regard to nitroglycerine in angina pectoris, Dr. Sawyer reports two cases, in one of which the drug did no good; in the other it produced very considerable relief. In the first case there was fatty heart; in the last, aortic stenosis and regurgitation. The drug was given as directed by Dr. Murrell, in one-drop doses of a one per cent. alcoholic solution in half an ounce of water.

The use of a combination of salicylate of soda with tincture of opium in diabetes produced very excellent results, some being practically well. No restrictions were put upon the diet in these cases.

A Bogus Medical College in Charleston, W. Va.—Dr. Simmons, member of the West Virginia State Senate, recently introduced resolutions revoking the charter of a wild-cat university, ostensibly located at Charleston, and known, by the provisions of its charter, as "The Livingstone University of America." This institution purported to be a medical school, and was a branch of one of Buchanan's institutions in Philadelphia.

Cremation in New York.—A bill to authorize the formation of cremation societies has been introduced into the State Legislature.

The State Charities Aid Association has begun its fight at Albany for an existence independent of the State Board of Charities.

Medical Night Service in Brooklyn.—The bill for establishing this service has been introduced and favorably considered.

Buffalo Insane Asylum.—A full investigation of this institution has been ordered by the Board of Managers, at the request of its superintendent. This investigation is to meet the charges of cruel treatment recently made by an ex-keeper.

United States Marine Hospital Service.—Drs. D. A. Carmichael, of Oswego, N. Y., and D. T. Armstrong, of St. Louis, who recently passed successful examinations for appointment into the Marine Hospital Service, have been appointed assistant surgeons by the Secretary of the Treasury, in the order in which they passed the Board. Assistant Surgeon Carmichael has been ordered to the Boston Marine Hospital, and Assistant Surgeon Armstrong to New Orleans. Surgeon P. H. Bailbache, Marine Hospital Service, has been ordered as inspector to the New England ports.

False Health Bills from Consular Officers.—Dr. W. H. Smith, health officer of this port, writes to the *Bulletin* of the National Board of Health, that during the past summer clean bills of health were issued by consular and health officers in the Bahamas and at Key West, after yellow fever had appeared in those places. Well-marked cases of yellow fever were taken from vessels entering this port in more than one instance during the past season, where consular declarations were invoked to prove that the disease did not exist at the port of departure, but subsequent evidence of its existence was secured. Much embarrassment had been caused during the past season by reason of the above facts.

A Medical Cabinet Officer.—The portfolio of Public Instruction in the new Italian cabinet has been accepted by Dr. Guido Baccelli, the distinguished professor of clinical medicine in the University of Rome. Dr. Baccelli has been among the most active of the numerous medical men in the Italian Legislature, and is a skilful parliamentarian as well as a prominent sanitarian and physician. He resigns his professorship, to which Dr. Panizza succeeds.

A Hospital Sunday Society has been recently formed in Lowell, with Dr. William Allen at its head. —*Boston Med. and Surg. Journal.*

Small-pox and Diarrhœa are visiting Chicago. Small-pox, at last accounts, was increasing in amount. The diarrhœa appeared as an epidemic. It was not violent in character. The cause assigned is bad sewerage.

Is Residence in Brooklyn Calculated to Aggravate or Induce Nasal, Laryngeal, or Bronchial Catarrhs? is the question investigated recently by the Committee on Hygiene of the Kings County Medical Society, and answered in the negative. Brooklyn is thought to be as healthy as New York in this respect, and New York to be as healthy as any seaboard city.

Vital Statistics in Spain.—There has never heretofore been any special attention paid to vital statistics by Spain. Recently, however, she has put herself at the head of all civilized countries in this regard by publishing a monthly statement of deaths, marriages, births, diseases, etc., for the whole country. The tables show that the mortality rate is 26 per 1,000, which is very high.

Foot-and-Mouth Disease in New York.—There has been a serious invasion of foot-and-mouth disease in England, it having been introduced from the North of France. Ten cattle affected with this disease were recently landed in this city, having been imported from England. They were promptly quarantined, a measure rendered very necessary by the actively contagious character of the disease.

The Number of Cases of Small-Pox in the United States, reported for the month of December, 1880, was 227. Of these 215 were in the Northeast.

The Origin of Enteric Fevers.—Dr. D. E. T., of Cheshire, Mass., writes: "I noticed in your issue of January 29th Dr. Anderson's article on 'The Origin of Enteric Fevers in Isolated Rural Districts.' In closing, he says: 'Let the readers of the Record speak and we shall have more light.' Last fall I was called to see a family some little distance from town. I found three patients in the same house, and all sick with typhoid fever. I examined the place carefully for a cause of this trouble. I found the drinking-water good. In the cellars—for there were two—I found a large quantity of rotten boards, decayed vegetables from the previous winter, a tubful of 'stinking' brine, etc., too numerous to mention. Just west of the house stood a privy, with no vault. Upon going into it, it contained 'scripture measure'—it was full to overflowing, not having been cleaned in two years. Every west wind must of a necessity waft that effluvia directly into the house, and who would care to inhale it? I would not, for one. I could find nothing else, and why need one look farther? In my opinion, the condition of those cellars and that privy produced that disturbance. There had been no typhoid fever in the house for nine years. A short time previous the entire family had the measles; one, however, that was afflicted with the fever did not have the measles. Again, I was called to see a family where four, in the course of a few weeks, came down with typhoid fever. Here the water was from a spring, a long distance from the house. North and northwest of the house were a large hog-pen and a barn-yard, while not twenty feet from the house, north, was a privy, the contents of which ran over, and, commingling with the waste water from the house-sink, extended over quite a surface. The cellar was in good condition. The sleeping-room of the one who first came down with the fever was on the north side of the house. Two of the patients became completely exhausted while taking care of the first two, and might not have had it but for irregular meals and sleep, and overwork. The seven made good recoveries. In the first family I mentioned, a hired girl, after a short time, came down with it elsewhere, having just left the family, and also ten weeks after the first began to get better. A family moved into the house, and two weeks later a little child, three years old, came down with the same fever. There had never been a case of typhoid fever in the second house I spoke of. There is not a doubt in my mind but what the emanations from those cellars and privies caused that sickness. Doubtless the two whose vitality had been lowered by the severe attack of measles, and the

two subject to so much fatigue, fell a more ready prey to the poisonous germs from the sources mentioned. There were no other cases in the town that came to my notice. Had any one of these died, without doubt we should have heard an eloquent sermon on the 'Providence of God,' while a choir would have sung, 'God moves in a mysterious way, His *wonders* to perform.' I do not deny that He does, but I do not believe that He moves through human excrement, and 'rotten' at that. The laws of nature are fixed and poison kills."

The Western Pennsylvania Hospital.—An examination for three resident physicians, to serve for one year from April 1, 1881, will be held at the Hospital Building, Pittsburg, Pa., on the fourth Wednesday of March, 1881, at 10 o'clock, A.M.

A Discussion upon the Prevention of Insanity.—The National Association for the Protection of the Insane will hold a parlor meeting, February 12th, when Dr. Stearns, Superintendent of Hartford Retreat, will open a discussion on the prevention of insanity, and how to check its alarming increase.

Small-pox in the West.—The spread of small-pox and diphtheria continues in Chicago, fifteen new cases of the former and as many more of the latter having been reported to the health authorities in one day. The readiness with which vaccination takes this year leads some of the local physicians to believe that the conditions are peculiarly favorable to catching the disease.

The *Journal's* Des Moines special, January 26th, says: "Small-pox has broken out in the Fort Madison Penitentiary, creating great excitement and panic. All the foremen of contract work have fled, and the work is generally abandoned. It is believed the disease will soon be under control.

Transfer of New York City Lunatic Patients to State Asylums.—A bill has been introduced into the State Senate, by Mr. Bixby, and ordered to a third reading, authorizing the Commissioners of Charities and Correction in New York, in their discretion, to transfer any insane person, heretofore or hereafter committed to any institution under their control, to any State or county lunatic asylum which has been duly licensed by the State Board of Charities, and whose managers will consent to receive the same. The expense of the maintenance of patients so transferred shall be fixed by agreement between said commissioners and managers, and shall be a charge upon the city of New York, together with the cost of transfer and the return of patients to New York when discharged.

Dr. Chas. F. Folsom, of Massachusetts, has been nominated by the President to be a member of the National Board of Health.

A National Veterinary Bureau.—The select committee of the United States Senate, to which was referred the various bills on the subject of pleuro-pneumonia and other diseases of cattle by direction of the committee, reported a bill for the establishment of a bureau of animal industry, and asked that the same be printed and recommitted to the committee.

Apropos of Surgical Malpractice Suits.—The Philadelphia *Medical Times* relates the following, which occurred recently in England: A servant-girl was suspected by her mistress of being *enceinte*. A medical man was sent for, and the girl examined. She afterward sued both mistress and doctor for assault and battery. The case was argued several times, elicited antagonistic rulings from different judges, and resulted in a non-suit in favor of her mistress, and acquittal by jury of the doctor. The patient swore she did not consent, but the jury seemingly did not believe her. The *Times* remarks: "Explorations of the purity of servant-girls would seem to be even more risky than the practice of medicine."

A National Commission on Adulterated Foods and Drugs.—A bill to create a commission of the above character has been introduced into the House of Representatives, by Mr. Gillette, of Iowa.

The New York Sanitary Reform Society in Albany.—The Senate Committee on Cities met January 26th and heard Charles Tracey, Jr., on the bill of the Sanitary Reform Society creating a street-cleaning department in New York, with a superintendent appointed by the Mayor for six years, at a salary of $6,000. No action on the bill was taken by the committee, as it is understood that Mayor Grace is preparing a bill for the same purpose, and the bill to be reported by the special Senate Committee on the Reduction of Expenses in New York also provides a new street-cleaning department. When all the bills are before the committee it will report the plan that appears to be most feasible.

Glucose as an Adulteration.—The blenders of cane-sugar and glucose will be up in arms against the bill introduced into the State Assembly by Mr. Root, of Monroe. It provides that any person or corporation engaged in the manufacture, refining, or mixing of sugar, syrups, or molasses for sale, who shall mix the same with glucose or grape-sugar, shall, before selling or offering the mixture for sale, mark the cask or package "adulterated," giving the percentage of glucose or grape-sugar contained in it.

Stamping Out Pleuro-Pneumonia.—Gov. Cornell has sent a special message to the Legislature in regard to the subject of pleuro-pneumonia among cattle. In it he refers at length to the importance of the subject, expresses the hope that State legislation will be supplemented by legislation at Washington, and that, while the national body is considering the matter the State Legislature should not relax its efforts to arrest the progress of the disease. Acting upon this message, the Committee of Ways and Means have recommended the passage of Mr. Skinner's bill, appropriating $10,000 for preventing the spread of pleuro-pneumonia.

Treatment of Asthma with the Induced Current.—Dr. I. Burney Yeo relates, in the *Lancet*, his experience at Neuenahr, where he saw the induced current used in the treatment of asthma. It sometimes acted like magic, curing the cases completely in a week or two. The electrodes are applied usually on each side of the neck, about an inch below the angle of the jaw. The current must be of good strength, so that the patient can feel the stream go across the larynx and soft palate. In bad cases it should be applied twice a day, from fifteen to thirty minutes each sitting. Dr. Max Schaeffer, who first advocated this treatment, found that the constant current never did any good.

A Congress of Laryngology is announced for September, 1882, in Paris. The members of the organizing committee nominated are MM. Fournier, Gouguenheim, and Krishaber.

Original Communications.

ON THE EARLY DIAGNOSIS OF SOME ORGANIC DISEASES OF THE NERVOUS SYSTEM.

By E. C. SEGUIN, M.D.,
NEW YORK.

(Paper read before Medical Society of State of New York, Feb. 3, 1881.

Probably no one would deny the desirability and utility of making an accurate diagnosis of disease at the earliest possible period, and one of the results of recent progress in the medical art is increased possibility in this direction. We can recognize diseases which, though existing, were unknown to practitioners of thirty or fifty years ago, and we can also determine the existence of some of these affections at a much earlier period of their evolution than we could ten or even five years ago. The sciences of semeiology and of diagnosis have unquestionably progressed greatly in the last generation, and this is more especially shown in the history of specialties, as ophthalmology, dermatology, gynecology, and neurology. I may be permitted to say that it is a duty and privilege of the specialist to inform the profession at large of the advances made in his department in diagnosis and therapeutics, in order to enable the general practitioner to apply the new knowledge, or the confirmed old knowledge, to the advantage of his patients.

It is with such a motive that I would call your attention to the possibility and desirability of an early diagnosis of two or three organic diseases of the nervous system. Probably I shall name no new symptoms, but will aim to call your attention to the really valuable symptoms of these affections, and to the significant grouping of these symptoms.

I have selected three affections which are now quite well known to us, and yet which, judging from my experience, are frequently ignored during long periods of their formative periods: I refer to posterior spinal sclerosis (progressive locomotor ataxia), dementia paralytica, and cerebral tumor.

I. *Posterior spinal sclerosis, or progressive locomotor ataxia.*

While willing to admit the occasional occurrence of abnormal cases of this disease, in which ataxia appears with little premonition, yet I claim that the general practitioner at the present day should diagnosticate the disease in the clearly defined first stage, or pre-ataxic period, which may last from a few months to several years. The vast majority of cases exhibit this first stage, and its symptoms are peculiarly characteristic, if not pathognomonic. In general terms the symptoms of this first stage consist in peculiar pains, and in reduction or abolition of reflex movements in different parts of the body, and from a combination of these a diagnosis of great probability of accuracy can be made years before the patient's gait becomes disordered.

If we assume that nineteen out of twenty victims of posterior spinal sclerosis pass through this neuralgic or pre-ataxic stage, we will not be far out of the way.

The pains of posterior spinal sclerosis are almost pathognomonic, especially when described by an intelligent educated patient. They have the following characters:

a. The pains are vagrant; they occur in innumerable spots in the affected parts—so much so that patients who have long had them are unable to fully enumerate the localities in which they have suffered; or, rather, they can hardly name a region which has escaped.

b. The pains do not, as a rule, occur in the course or distribution of recognized nerve-trunks or branches; they are local pains, and this peculiarity may serve (with *a*) to distinguish between the pains of sclerosis and those of true neuralgia (sciatica, etc.).

c. The seat of pain is commonly in an area of skin varying in size from that of a pea to that of a small hand. In many cases pains are also referred to the muscles, to the vicinity of bones, and even to articulations and viscera.

d. The pains are paroxysmal in a completely irregular manner: they may occur every few moments for hours in one spot, or may be altogether wanting for weeks; or at times a single pain is the signal that the disease is not cured. It seems probable that the atmospheric disturbance which precedes a storm (areas of low barometer) causes an increase in this symptom, or even calls it forth.

e. The pains are sudden and vary in severity from the sensation caused by the penetration of a small knife-blade to what we may imagine to result from tearing through the tissues with a hook or large knife; or the sensation is like a painful electric shock. Perhaps most of the pain in such cases is in the shape of stabbing pains in an ovoid or round area of the skin (foot, thigh, arm, shin, etc.), repeated every few seconds for hours or even a day or two. The suffering is often such as to make the strongest-willed man writhe and shriek. The description of the pains, *i.e.*, their comparison with known sensations or physical conditions, varies greatly, according to the fertility of the patient's imagination and his command of language. From their suddenness and electric character the pains of posterior sclerosis are often called fulgurating or terebrating. The seat of pain usually is hyperalgesic, *i.e.*, painful to the lightest touch during the paroxysm; yet firm pressure sometimes gives relief.

Second.—Diminution of various reflexes throughout the body.

This is best observed in the iris and at the patellar tendon, though the constipation and imperfect micturition which are such frequent symptoms of the disease are phenomena of the same order.

a. The impairment of iritic reflex action ("pupillary reflex") was first intelligently studied in 1869 by Dr. Argyll Robertson, of Edinburgh. His observations have since been abundantly verified by numerous observers, and an exhaustive paper on the subject has been published by Prof. W. Erb, of Leipzig, in the *Archives of Medicine*, October, 1880. Robertson and others after him noticed that the pupil of tabetic patients did not dilate in the shadow and contract in the light, as do normal pupils; and they further observed that during the effort of accommodation there occurred a normal pupillary contraction. In other words, the reflex iris movements were abolished, while its associated quasi-voluntary movements were preserved. These phenomena I have observed in almost all my patients suffering from posterior spinal sclerosis, and I am in the habit of calling the attention of students to the symptom. In two of the patients now under my care this condition is not present, but there have been cases of abnormal sclerosis, in which all the symptoms appeared in a most irregular manner.

The pupils in a suspected case of posterior-spinal sclerosis are to be tested in the following manner: the patient is placed, seated or standing,

facing a brightly illuminated window, and told to keep his look fixed on some distant object, such as a house or tree. By alternately closing and opening the lids, or better, by shading the eyes with one's hand momentarily, it is easy to see if the pupils change diameter. It is of the utmost importance that the patient's intelligent assistance be secured, in order that his gaze shall remain adjusted for distance. In a given case the absence of reaction to light having been noted, we next hold up one finger or a small object within a foot of the patient's face and bid him look at it. At once the pupils contract and do so in proportion to the accommodative effort and the coincident convergence; when the patient looks at the distant object, and relatively or absolutely relaxes his accommodation, the pupils dilate again.

The finding of such a condition of the pupil—the existence of *Robertson pupils*, if you will allow the expression—is now considered of nearly as much importance for diagnosis as the occurrence of fulgurating pains.

b. Diminution and abolition of reflex action in the peripheral apparatuses is best studied at the knee.

We test the so-called patellar reflex or knee-reflex or patellar tendon-reflex in the following ways: the patient being seated, is told to cross one leg over the other in a natural manner, and to let the muscles relax; or seated, we place our left hand under the popliteal space, tell the patient not to help us, to let the leg hang loose, or, in popular parlance, "dead," and lift the whole limb so that the foot swings a couple of inches above the floor; then we tap the skin over the whole of the region from the insertion of the quadriceps femoris to the tuberosity of the tibia, with one or two finger-tips applied as in percussion. The place whence a reflex quadriceps contraction is most apt to occur is about midway between the lower end of the patella and the tibial protuberance. The taps should be gentle at first, and if these fail, harder ones are to be tried. A third mode of procedure, which is very good indeed, is to seat the patient on a table so that his legs dangle some two or three inches beyond its edge; then we tap the patellar region as above described, without supporting the thigh with our left hand. The test may be well done through the patient's clothing, yet it is desirable, especially in doubtful cases, to tap the bare skin. Another important precaution is to secure the absolute relaxation of the patient's muscles, and to divert his attention from what you are doing. Even with all precautions it is sometimes next to impossible to secure this indispensable muscular relaxation. In the healthy subject this test develops a contraction of the quadriceps extensor femoris and causes an extension of the leg, or a sudden jerk. In a very early stage of posterior spinal sclerosis no contraction takes place.

I would also call attention to the occasional occurrence of reflex movements of the thigh produced by contraction of the iliac group of muscles during the knee-test. I have an example of this distant reflex action in a typical case of sclerosis of the posterior columns, in which the quadriceps does not contract at all.

While claiming very great diagnostic value for this negative symptom, I would not be understood as attaching pathognomonic significance to it, as we all know that there are a few seemingly healthy individuals in whom the patellar tendon-reflex is lacking, and also that there are other diseases which diminish or abolish it. Indeed, I may say that I recognize no pathognomonic symptom, and even in attempts to push diagnosis to an extreme delicacy, would urge that reliance be placed on the grouping of symptoms, rather than on any one of the signs, however constant and important it may appear.

Physiologically analogous to this condition of loss of tendinous reflexes is the flabby state of the muscles in the affected parts. This is not due to any positive atrophy, as electrical tests show us marked departure from the normal reactions; but to impairment of what physiologists call muscular tonus, a state of partial contraction or tension of muscles which is kept up by the inevitable and continued excitation of the cutaneous nerves by air, clothing, surrounding objects, etc., acting in a reflex way through the spinal cord. It has been recently claimed that this loss of muscular tonus was the most important factor in the production of the ataxic movements which characterize the second stage of the disease.

The vesical and rectal reflexes are diminished in posterior spinal sclerosis. Slow, irregular micturition is complained of by most patients, in the first stage and in the second. We usually micturate without using much volition, but the tabetic patient is obliged to strain and to try hard to pass water. Defecation is, like micturition, a semi-voluntary act, and in the late first stage of the disease in question constipation becomes more and more marked, and that through loss of the automatic or reflex action of the rectum and adjacent muscles.

The sexual act is, in my experience, frequently impaired and sometimes almost lost before the second stage sets in. The acts of erection and emission are usually brought about in a reflex manner by irritation of the skin and mucous membrane of the genitals. As a result of diminished spinal reflex action we have imperfect erections, and either premature emission, or, what is more common, I believe, very slow production of the orgasm, and impossibility of repetition within a reasonable time.

Some writers admit abnormally great sexual power in the early stage of tabes, but I am not sure to have met with more than one or two cases in which this seemed to be the case. In one of the patients, a female, I became convinced that her extraordinary capacity for sexual intercourse was not in a strict sense pathological or pre-tabetic, but had been marked in one shape or another from childhood.

It seems reasonable at the present time to advance this general proposition: that in posterior spinal sclerosis the various reflex actions performed by means of those portions of the cord which are the seat of sclerosis, are diminished or lost; or, to put it in another way more useful for practice, it may be said that the limitations of loss of reflex action in different parts of the body accurately indicate the limits of sclerosis in the posterior sensory apparatus in the spinal axis.

Third.—The occurrence of paralysis of ocular muscles.

A very large proportion of tabetic patients tell of past or present diplopia, and in a certain number of cases the ocular paralysis precedes the pains and ataxia by several years. So true is this statement, that it has become an established practice with neurologists and ophthalmologists to suspect posterior spinal sclerosis in adults who present themselves with strabismus, diplopia, or ptosis. In such a case we should carefully question the patient about the occurrence of fulgurating pains, test the pupillary and tendinous reflexes. I need hardly add that another obligatory line of inquiry in such cases is with reference to symptoms of syphilis.

The same remarks apply to atrophy of the optic nerve, which is occasionally an early symptom.

I have not the time to refer to the gastric, laryngeal and rectal crises and the peculiar forms of arthritis which once in a while occur early in the disease.

It seems to me that, by a critical appreciation of the above symptoms in a patient, the diagnosis of the first or neuralgic stage of posterior spinal sclerosis is as certain as the diagnosis of any internal disease, not excepting such affections as pneumonia or valvular cardiac disease. Several autopsies are now on record, made during this first stage, and in these sections of the cord showed sclerosis of the posterior columns. I have one such observation of my own: fulgurating pains for about thirty years, absence of patellar reflex while under observation (two years), dilatation of one pupil, no trace of ataxia. The sclerosis of the posterior columns in this patient's spinal cord is visible to the naked eye.

It is often objected that the pains of ataxia are not absolutely reliable for diagnosis. This may be true when the patient is stupid, or when the physician is not careful to ascertain the precise character of the pains.

The only two conditions in which pains somewhat resembling fulgurating pains occur, in my experience, are paralytic dementia and gout. In the former disease, slight fulgurating pains—"smaller" pains, if I may be allowed the expression—are described by the patients; but in many of these cases autopsy shows that, besides the cerebral lesions proper to the disease, the posterior columns of the cord exhibit pathological alterations; so that these cases are, after all, *quasi*-tabetic. The sharp pains of gout are short, stabbing pains in the skin of various parts of the body, compared by the patients to the prick of a needle, cold or hot. There is no tendency to repetition of the pain in one spot for hours or days; the sensations appear in various parts of the body, and are bearable. It is but right to add that this statement is based on very few observations, and requires verification.

The differential diagnosis of fulgurating pains from the pains of neuralgia, strictly speaking, is very easy. In neuralgia the pain is in the course and distribution of one or two (seldom) nerve-trunks and their branches; it may be paroxysmal, but does not assume the excessive irregularity of the tabetic pains—agony for a few hours, and freedom from pains for hours, days, or weeks. The hyperæsthesia in fulgurating pains is at the seats of pain. In neuralgia we find regular "tender points" along the nerve-trunk, or where its branches become superficial. The lightest touch causes pain in the painful districts in tabes, while the tenderness of nerves in neuralgia is usually demonstrable only by firm, localized pressure. Further, true neuralgia is seldom bilateral, while it is the rule for fulgurating pains to appear on both sides of the median line—in both lower extremities, for example. A last important distinction is that neuralgia is relievable or curable, whereas fulgurating pains are practically incurable, and are fully relieved only by morphia-injections.

The confusion so often made between "rheumatism" and the first stage of sclerosis is even less pardonable. Of course no practitioner would mistake fulgurating pains for articular rheumatism; the error is with respect to "rheumatism," so-called, affecting muscular masses, and aponeuroses. In these affections the pains are usually dull, nearly constant, and distinctly aggravated by movements. Pressure must be firmly made upon the parts to produce pain, whereas in fulgurating pains the condition is one of cutaneous hyperalgesia under a slight touch. Again, this "rheumatic" condition is distinctly amenable to treatment (counter-irritants, etc.), whereas the pains of posterior spinal sclerosis are, in one sense, incurable.

II. The second disease of the nervous system to which I would direct your attention as the object of more exact and earlier diagnosis is *paralytic dementia*. By this term is meant the passive form of an affection which consists in peri-encephalitis, adhesion of the meninges, and various secondary degenerative changes in the brain and in the posterior columns of the spinal cord. Chronic peri-encephalitis also presents itself in an active or delirious form, which is known as general paralysis or paresis. In neither form is there a positive condition of paralysis at any time, except as a complication from the occurrence of cerebral hemorrhage or softening. Both the semeiological names, paralytic dementia and general paresis, are, strictly speaking, misnomers; yet we accept them as sufficient.

The semeiology of peri-encephalitis is complicated, and it would be beyond the scope of this essay to describe it in detail. I merely wish to call your attention to the symptoms which, in my opinion, are earliest in their appearance and significant of an incurable disease. These are tumors or fibrillary contractions in various muscular groups, especially in the tongue, facial, and brachial muscles; a tremulous, thick, and vibratory speech; inequality of the pupils; dementia.

The tremor of paralytic dementia probably first makes it appearance in the facial and lingual muscles. It consists in non-rhythmical contractions of small muscles or of fasciculi of muscles, which are either present in the quiescent state of the features, or are excited by emotion or by the performance of a voluntary movement, as showing the tongue or the teeth. Sometimes innumerable fine fibrillary tremors cover the face, while in some cases the movements are coarser and irregular enough to merit the term choreic. The tongue exhibits both sets of tremors—the very fine fibrillary ones and the large choreic oscillations. There is also, though usually at a later stage, some shrivelling or atrophy of the tongue.

The hands are tremulous, usually in a fine semi-rhythmical way. This trembling is sometimes scarcely visible, but is perceptible as a delicate parchment-like fremitus on holding up the patient's extended fingers between ours. In the lower extremities the tremulousness is not apparent.

The speech is affected as a result of this tremor and as the result of a certain want of co-ordination in the muscles of articulation. Words are quickly spoken, with some syllables omitted or blurred, or with a terminal syllable left off. The articulate sounds which are produced are heard as vibratory or tremulous, and the speech seems thick. Patients semi-unconsciously avoid long or difficult words in conversation, and even seek roundabout ways of expressing their meaning by shorter words. Besides this vibratory tremulousness in articulation there is an imperfection in the pronunciation of words, long words especially. Remedy is pronounced "remdy;" constitution, "constution;" infallibility, "infallaby." The last syllable may be badly sounded or even omitted. I have known this characteristic speech to be the only well-marked symptom, and to be followed by dementia, exaltation, etc. Occasionally a patient comes to us complaining of this defective articulation. I now recall two such cases, one of which died three years later in a German

private asylum, with all the symptoms of general paralysis.

Just as spoken language is affected by the facial and lingual tremor, so is the handwriting altered by fibrillary contractions in the muscles which govern the movements of the fingers. A tremulous, jagged, wholly irregular handwriting results, and in some cases, where dementia is present, words or syllables are frequently omitted in composition.

The pupils in paralytic dementia are either very small or irregular, usually the latter. The reaction of the iritic muscle to the influence of light may be diminished or abolished.

I may here say, by way of parenthesis, that small and unequal pupils in a person of middle age, from twenty-five to sixty, should lead to an inquiry into the possible existence of one of three morbid states, viz.: paralytic dementia (or general paralysis), sclerosis of the posterior columns, cardiac or aortic disease (intrathoracic disease).

In my experience, the patellar tendon-reflex is often increased in paralytic dementia.

The dementia or failure of mental power is sometimes impossible to detect until after the more peripheral, physical symptoms have existed for some time. It is possible for the psychical symptoms to precede the physical; sometimes the two appear to develop simultaneously; usually, I believe, the physical symptoms already studied are apparent for months before the mind shows decay.

Dementia is evidenced by impairment of memory for recent events, by loss of the power of comparison, and consequently of judgment. Many of the automatic or quasi-automatic acts of every-day life which form a part of the patient's manner and individuality are badly performed or omitted. This leads to what is known as change of character in the subject; he becomes less neat in his attire or personal cleanliness; he loses his table-manners, handling his spoon, fork and knife awkwardly, soiling his clothing with drippings of food, etc. This impairment of judgment is probably one of the factors in the immorality and tendency to alcoholic indulgence which are so frequent in this disease.

Yet, in the midst of this increasing moral wreck, so visible to the immediate relatives of the patient, there may remain a degree of correctness in thought and success in every-day occupation which may impose upon strangers, and even upon a judge and jury. The things which the patient is in the habit of doing every day, and about which he has thought many years, such as professional work and business transactions, may be fairly well executed, while the tremors, pupillary irregularity, impaired articulation and handwriting, together with alteration of moral character, make the medical observer recognize a fatal, progressive disease of the brain. These cases come more frequently under the observation of general practitioners than under that of the specialist, whether asylum physician or neurologist. They are very frequently in our midst, and their early recognition may save much disgrace and impoverishment to families, though, alas! it does not pave the way for more successful therapy.

I would repeat, that a person exhibiting tremors of the facial muscles of the tongue and hand, a vibratory and slurred speech, angular or tremulous handwriting, and irregular, small pupils, should be suspected of having chronic peri-encephalitis or paralytic dementia. The addition of gradual failure of mind—dementia—makes the diagnosis certain. In case there should be superadded exalted notions, with maniacal attacks and epileptiform seizures, the case deserves the name of general paresis, and as such is the form more usually seen and studied by asylum physicians.

It has been claimed in the last few years by Fournier and others that cerebral syphilis, in the shape of arteritis, partial arachnitis and localized peri-encephalitis, might give rise to the symptoms of paralytic dementia. I am in accord with Dr. Julius Mickle and others in believing that it is often possible to distinguish the idiopathic from the syphilitic dementia. The latter is, comparatively, much more acute (or rather less chronic), in its development; in it we do not observe the very fine muscular tremors as an early symptom; the pupillary disturbance consists usually of mydriasis of one side, with or without other signs of third-nerve palsy; the speech defect is a coarse thickness in pronunciation, rather than a vibratory, tremulous sound, which, when once heard, can never be forgotten. There are well-marked paralytic symptoms, usually hemiplegic, and decided epileptic phenomena in syphilitic cortical diseases. The dementia is seemingly more profound, causing an apparent imbecility with want of control over the sphincters. Altogether, the symptom-group is much more threatening in appearance, yet great improvement or even apparent cure may be obtained in very bad cases by the use of mercury and the heroic dosing by iodide of potassium. This therapeutic proving of a disease is of course valuable in practice, but logically it cannot be termed a diagnosis, and it is a reproach to the present state of our science that in several types of disease we should be obliged to resort to it.

III. The third organic disease of the nervous system which should, it seems to me, sometimes be recognized with positiveness much earlier than it now is, is *tumor of the brain*.

In making this statement I am perfectly aware that some cerebral tumors produce no distinct or special symptoms during life, and that others produce incongruous and apparently paradoxical symptom-groups. Some years ago, before the physiology of the brain was as well understood as it is now, we could offer no explanation of these perplexing cases which seemed to destroy our rules of diagnosis. To-day we have acquired an approximately correct knowledge of which portions of the brain (cerebrum especially), are excitable and capable of causing symptoms, and which are inexcitable, and may be the seat of extensive disease without clear indications. This I say without reference to the finer localization theories of the last five years. We know quite positively, for example, that extensive lesions may exist in the anterior and inferior portions of the frontal lobes, in the sphenoidal lobes, and in the occipital lobes of the cerebrum, and in one-half of the cerebellum, without causing any symptom specially useful for diagnosis, such as will be considered later on. We have also learned, from Flechsig's researches, that the decussation of the motor tract just below the anterior pyramids of the medulla oblongata is variable in amount, and that in some cases there may be no crossing of fibres, or hardly any. This important law of variability in the pyramidal decussation enables us to correctly appreciate the rare cases in which a cerebral lesion produces symptoms (paralysis or spasm) on the same side of the body as itself—cases which have been so urgently pressed upon the profession by Brown-Séquard in the last ten years as proofs that our physiological laws of cerebral action and of the productions of

symptoms were all wrong. These laws stand to-day, I believe, only strengthened by the exceptions which have been adduced.

All I wish to say is that tumors located in what we now term the excitable region of the cerebrum or the motor zone, are capable of very early recognition.

The region which receives the name of motor zone is irregular in shape, and perhaps its limits are not yet well ascertained. In a general way we may say that it includes the median region of each hemisphere, in particular the posterior extremity of the third frontal convolution, the upper half of the second and first frontal, the ascending frontal and ascending parietal convolutions, the anterior gyri of the island of Reil, the paracentral lobule on the inner surface of the hemispheres, and, perhaps, a large part of the upper set of parietal convolutions. These are the motor convolutions, and embrace the so-called motor centres of Ferrier. Besides, we must include under the name of motor zone, or region, those fasciculi of white substance which connect the above-mentioned gyri with the crura cerebri, constituting the anterior half (or less) of the internal capsule as it passes between the nucleus lenticularis on the outer side and the nucleus caudatus and thalamus opticus on the inner side.

The succeeding remarks apply to tumors which involve any of this large expanse of cerebral substance, either in its external gray matter or in the fasciculi of white substance lying between the motor convolutions and the central gray bodies.

The symptoms which I think are characteristic of tumor in the motor zone of the hemispheres are:

Localized convulsions in peripheral muscles; equally localized paralysis of peripheral parts; neuro-retinitis or choked disk; localized headache. The symptoms are named in the order of their frequency and importance.

The initial convulsions of cerebral tumor are sometimes restricted to one side of the face, one hand, or even two fingers, or one leg. The spasm is usually tonico-clonic, but may be wholly clonic or jerky. In many cases this localized spasm is unaccompanied by loss of consciousness or vertigo, and it may remain localized in the part first affected during many attacks, extending over weeks and months of time. The patient feels the muscular contraction before it becomes evident, thus constituting a sort of aura. In some cases almost from the first, in nearly all cases after a while, the convulsion involves more muscles on one side of the body; it seems to ascend or descend, to use the patient's expressions, and there results a hemiplegic epileptic attack with loss of consciousness. Again, the attack may begin in a small peripheral part, involve the whole of one side of the body, and later affect the opposite side, thus constituting a full epileptic attack. The patient is able to watch the progress of the spasm for a number of seconds or minutes before losing consciousness or being thrown down, and we may take advantage of this peculiarity to instruct the patient in the use of the tourniquet or bracelet, placed on the limb just above the seat of first spasm, to cut short the attack by pressure.

This distribution of spasm, and its possible occurrence without loss of consciousness, are signs which most positively distinguish these symptomatic convulsions from the ordinary epilepsy which we constantly encounter.

As early as 1827, a French physician, Bravais, described the hemiplegic form of epilepsy and showed its relation to gross cerebral disease; but it is to Hughlings Jackson, of London, that we owe the physiological study of these cases, and of cases of more limited epilepsy, and the first demonstration of the dependence of localized spasms upon limited lesions of the opposite cerebral hemisphere.

Indeed, in prosecuting these clinical and post-mortem studies, Hughlings Jackson laid the foundation for the vigorous hypothesis of cerebral localization, as Ferrier states in the dedication of his book on the "Functions of the Brain" to this illustrious physician. So far as my own experience goes, autopsies have invariably verified the theory of localized epilepsy which I have stated, and the journals of the last five or six years contain numerous corroborative cases. As the evidence now stands, chronic localized convulsions must be looked upon as almost positive indications of a localized lesion in the opposite cerebral motor zone, most probably a tumor.

What I have said of localized convulsions applies to localized paralysis. It, like spasm, may be limited to a small muscular group, or to one half of the body; it may begin in a part and gradually extend. In general terms paralytic phenomena follow in the wake of the convulsions at a distance of weeks or months, and have the same distribution.

Neuro-retinitis, or choked disk, is a frequent result of tumor within the cranium, but this symptom may, on the one hand, be absent with a large or even monstrous cerebral sarcoma, and on the other, it does not afford any indication of the locality of the tumor. The notion which was current a few years ago, that neuro-retinitis was pathognomonic of cerebral tumor, is wholly without foundation.

From my observations I am led to conclude that the occurrence of localized convulsions and paralysis, without choked disk, is valuable evidence of tumor, while choked disk without localized spasm and paralysis is merely a basis for suspecting tumor. The association of the two sets of symptoms makes up almost positive proof of the existence of a neoplasm. A diagnosis based on this symptom-group is quite as secure as that of any other disease giving rise to local physical signs.

The value of headache, of localized cranial pain more strictly speaking, is also variable. By itself it is not strictly indicative of tumor, but with either the choked disks or with localized motor disturbance it becomes highly significant.

The co-existence of the three symptoms justifies a positive diagnosis of cerebral tumor.

Had I more time I should like to speak of the possibility of a still finer diagnosis in cases of tumor of motor districts of the brain. We are sometimes enabled, through recent advances in experimental physiology and pathological anatomy, to localize tumors within an inch or two of their actual situation, in the regions known as centres for speech, centres for the face, centres for the arm and hand, centres for the leg, and centres for both arm and leg. The future of neurological medicine is pregnant with discoveries in this direction, which will have very practical application.

My purpose in embracing the opportunity of addressing you was to make a sketch of the scientific and logical basis for progress in the direction of early diagnosis.

The affections whose semeiology we have studied —cerebral tumor, paralytic dementia, and posterior spinal sclerosis—are as yet incurable. Yet, if we can ever hope to apply remedies to them successfully, it will have to be done at the earliest moment when their recognition is possible by the general practitioner, who naturally has charge of the cases in their incipience.

FRACTURE OF THE RADIUS IN THE CADAVER.

EXPERIMENTS BY JNO. H. GIRDNER, M.D.,
LATE HOUSE SURGEON TO BELLEVUE HOSPITAL, NEW YORK.

THE paper read by Dr. Pilcher before the New York Academy of Medicine, and published in the MEDICAL RECORD, July 27, 1878, and the experiments made and detailed by Prof. Hamilton in his book on fractures and dislocations, are the only ones which to my knowledge have been made of late years to discover precisely what occurs when the lower end of the radius is broken. In both these series of experiments, adult subjects were selected, at the suggestion of Prof. Frank H. Hamilton; therefore, I made the experiments which are detailed below, and some of the specimens which were preserved, may be found in his cabinet.

The first series of experiments made by me, were upon still-born subjects, or upon those who had died within a very few days after birth. The back of the arm and elbow of the subject being laid upon the table, the fore-arm was flexed to a right angle, which brought it to a perpendicular position, and forced dorsal flexion produced by carrying the hand backward.

When the back of the hand had been brought nearly in contact with the dorsal surface of the forearm, something was felt to give way, and the wrist at once assumed the silver-fork appearance so characteristic of a Colles's fracture. I then made a careful dissection of the radius, and found a separation at the epiphyseal junction. This junction was about three-fourths of an inch from the radio-carpal articulation, and the epiphysis had been thrown backward on the lower end of the bone, and occupied the same position which the lower fragment does when the experiment is made on an adult subject. The separation was so complete that when the ligaments and fibrous tissues around were cut, the two fragments at once fell apart. The next series were made upon subjects from nine months to one year old, and the same dorsal flexion was produced as in the preceding experiments. In these cases, when the hand had been carried back until it laid on the dorsal surface of the forearm, it was liberated and allowed to seek its own position, which it did—slowly coming back into line, which, however, it failed to reach. The deformity was not nearly so marked as in the first series, nor sufficient to indicate a fracture; but, when compared with the limb of the opposite side, considerable deformity could be noted, but not so great as in a Colles's fracture. A careful dissection of the radius proved the epiphyseal junction in this case to be less than one-half inch above the articulation, and the bone for an inch above the junction of the epiphysis was exceedingly cancellous, and rich in animal matter. About one-fourth of an inch above the junction of the epiphysis was the point at which the force used in the dorsal flexion had expended itself—not, however, resulting in a fracture, but in a bending of the bone, which, from the extreme point to which the hand was flexed, could not have been less than a right angle. The line of the bending could be distinctly made out, although the elasticity of the bone had brought it almost to a straight line.

The subjects of the third series of experiments were from three to seven years old; and as I have done in the other series, I shall describe what occurred in the case the specimen of which is in Dr. Hamilton's cabinet, the others of this series in no way differing from it.

The subject was two years and six months old, and a female. Forced backward flexion was practised as before, the hand being carried back to the forearm; this required more force to accomplish than in the other series, nor was there at any time during the flexion a sensation of yielding of the resistance. When the hand was liberated it returned quite rapidly to its normal position, nor could any deformity be made out.

A careful dissection showed that I had neither bent nor broken the bone; but I had stretched and partly ruptured the anterior ligament of the wrist-joint, and especially that fasciculus of it known as Pilcher's ligament. Ossification of the epiphysis in these cases was far advanced. Other experiments were made, the subjects being fifteen and eighteen years old. In these, however, as in adults, when forced dorsal flexion was applied to the hand, the lower end of the radius was broken, generally with an audible snap, the hand and wrist assuming at once the silver-fork deformity.

I will not enter into an account of what was revealed by dissection when the subject was over fifteen years old, as Pilcher and Hamilton have already done so very fully.

Now, the conclusions which are deducible from these experiments are:

First.—That, for the first few months of life, the epiphyseal junction is about three-fourths of an inch from the radio-carpal articulation and that, if sufficient force be applied in a direction which in the adult would produce a Colles's fracture, there will be a separation of this epiphysis, and the hand will present that deformity which is seen in Colles's fracture.

Second.—That, between the ages of nine months and one year the epiphyseal junction is within half an inch of the wrist-joint, and forced dorsal flexion will not produce a fracture of the radius, nor a separation of the epiphysis, but a bending of the bone about one-fourth of an inch above the epiphyseal junction, and the hand, left to itself, returns partly to its normal position, and the deformity is slight.

Third.—That, from the third to the seventh year of life (and perhaps to the tenth), the epiphysis of the lower end of the radius has almost completely changed to an apophysis, and forced dorsal flexion will neither bend nor break the radius, but will cause a stretching and partial rupture of the anterior ligament of the wrist-joint, and especially of Pilcher's ligament.

Fourth.—That, after the fifteenth year, and perhaps earlier, forced dorsal flexion will produce Colles's fracture with characteristic deformity.

METALLIC MERCURIAL OINTMENT IN OPHTHALMIC PRACTICE.—Dr. Wolfring recommends the use of an ointment composed of one part of metallic mercury to three parts of vaseline—a little of which is to be placed in the conjunctival sac twice daily, the eye beng afterward closed and bandaged—in the treatment of various diseases of the eye: circumscribed infiltrations of the cornea, plastic inflammations of the iris, posterior synechia, recent choroiditis, cataract, etc.—*Medycyna*, 1880, No. 32.

PREPARATION FOR CORNS.—Jazow recommends to paint the corns with the following preparation: R. Extr. cannab. indica, 5.0; acid. salicyl., 20.0; collodii, 240.0. In all cases where it was used, the corns rapidly disappeared.—*Vratch Vedomosti*, No. 437.

SKIN-GRAFTING IN LOSS OF SCALP.

By WILLIAM L. BRADLEY, M.D.,

NEW HAVEN, CONN.

In 1869, M. Reverdin, of Paris, France, made known the process of skin-grafting, and it soon became recognized as the best method of healing large granulating surfaces. In cases where the entire scalp has been torn off, the success of this method has attracted especial attention. The following case is believed to be the second of its kind occurring in the United States, and with the first, which was under the care of the late Dr. L. C. Bartlett, of Waterbury, Conn., was partially published in the "Transactions of the Connecticut Medical Society for 1874." In answer to inquiries, and to assist others in the treatment of similar cases, it is now published in a completed form.

On the 8th of August, 1873, Ann Farley, aged thirty-five years, of robust constitution, had her hair caught by a revolving shaft, which tore off the entire scalp. The tear extended below the right eyebrow and down upon the right cheek; the pinna of the right ear was also removed, and the pericranium covering the vertex was injured to such a degree that, afterward, the outer table of the skull exfoliated for a distance of seven inches. Immediately after the occurrence of the accident the case came under the care of Dr. Ira Smith. Dr. S. replaced the scalp, but in four days was obliged to remove it. The exfoliation of bone was hastened by the application of nitric acid, but more than three months was required for its entire removal. Dr. S. implanted a considerable number of grafts, but, probably on account of their large size, being an inch in diameter, and possibly for other reasons, none of them became permanent.

After nearly four months had elapsed, the patient, who had entered the New Haven Hospital, came under the care of the writer, who continued in charge until the wound was entirely healed. At this time, December 1, 1873, the unhealed surface measured seventy-four square inches. The growth of healthy granulations was so stimulated by the application of basilicon ointment, that, December 10th, several pieces of skin, removed from the patient and others, were successfully implanted. During the following five months the grafting was repeated at varying intervals, but the process of healing was retarded by several attacks of erysipelas. May 28, 1874, the progress of the case was exhibited to the Annual Convention of the Connecticut Medical Society. At that time the newly formed skin had advanced from one to two inches beyond the usual marginal cicatrization. The denuded surface was entirely healed September 22, 1875, completing a period of two years one and a half month from the time of the accident. This result was accomplished by grafting seven hundred and ninety-five pieces of skin, which measured from a quarter to an eighth of an inch in diameter, and were removed from fifty-five individuals; of this number, one hundred and seventy-one were contributed by a strong and healthy young man, who was resident in the hospital, and one hundred and fifty by the patient. It is estimated that about one-third of the entire number failed to become permanent.

Constitutional treatment.—The marked dependence of the condition of the wound upon the state of the general health rendered necessary the continuous employment of supporting measures. The tincture of chloride of iron was used as a blood alterative almost constantly, either to relieve or to ward off the tendency to attacks of erysipelas. The loss of blood attending the monthly flow usually resulted in the destruction of the more recent grafts, and the growth of others which had become permanent was temporarily arrested.

Condition of the granulating surface.—Granulations which were small, florid in color, and in the first stage of their growth, were found to possess an adhesive property which was peculiarly favorable to successful grafting. After the first few months the use of stimulating applications was discontinued, because of their tendency to produce large and coarse-textured granulations. Even under the employment of simple cerate, which proved to be the best ordinary dressing, it was found necessary to repress hypertrophy of the granulations by frequent applications of lunar caustic.

Mode of transplanting.—The temperature of the apartment in which skin-grafting is to be performed should be about 70° F. In preparation for the reception of grafts, the denuded surface was cleansed with a camel's-hair brush dipped in tepid water; a method of importance, because even a slight effusion of blood was found liable to prevent union between the grafts and the granulations. A piece of skin was seized, not bruised, with a pair of fine-toothed forceps, and, when removed with curved scissors, it measured from a quarter to an eighth of an inch in diameter. The graft was flattened out upon the finger-nail, and both of its surfaces were gently scraped to free them from blood, minute hairs, and loose epithelium. Having been pressed down upon, and sometimes between the granulations, the grafts were covered with oiled gutta-percha tissue, surmounted by cotton batting, and supported by a cap of cotton or flannel cloth. As a method for holding the dressings in place, strips of adhesive plaster were found to cause unpleasant pressure, and to impede the circulation of blood. The number of grafts was only limited by the supply and the extent of the healthy granulating surface. On sixty-six different occasions, an average each time of thirteen grafts were transplanted. In accordance with the observation of others, grafts were found more likely to grow in proportion as they were placed near the margin of the wound, or adjacent to other grafts which had become permanent. The dressings were retained until the third day, and great care was required lest the grafts should be disturbed by the daily dressing of other parts of the wound. It was observed that grafts which lived and became permanent, but did not grow, retained very closely their original appearance, while others, which did grow, could not be distinguished from the outgrowth of fibro-cellular tissue which surrounded them. When the grafts were placed in near proximity, the newly formed skin appeared to be stronger, and cicatricial contraction was entirely avoided. This was especially noticeable in the treatment of an ectropion of the right upper eyelid.

Operative Treatment for Infra-maxillary Neuralgia.—Dr. Perkowski has cured a case of obstinate neuralgia of the infra-maxillary nerve by dividing the horizontal branches running from the auriculo-temporal nerve to the external ear. The mouth being slightly opened, he made a vertical incision between the articular process of the maxilla and the auricular cartilage.—*Medycyna*, No. 40.

SOME REMARKS ABOUT

TERTIARY SYPHILIS OF THE THROAT AND ITS TREATMENT.

By WHITFIELD WARD, A.M., M.D.,

PHYSICIAN TO THE METROPOLITAN THROAT HOSPITAL, NEW YORK.

In no other portions of the human organism are the special manifestations of syphilis so perfectly portrayed as in the upper air-passages, where we constantly see inflammatory swellings, destructive ulcerations, new formations, perforations, and disfigurements from adhesion, a series of phenomena which render this disease peculiarly interesting. To the busy practitioner, who may have neither the time nor the opportunity to pursue a course of investigation into this variety of throat-affection, a perusal of the cases submitted below may be of some practical use. The cases referred to have been selected from a large number which I have met during the past year in both hospital and private practice.

Case I.—*Paralysis of Adduction of both Vocal Cords Producing Complete Aphonia.*—A young girl, aged eighteen years, applied for treatment at my office about nine months ago, complaining of inability to talk above a whisper. Upon laryngoscopic examination the cause of her trouble was easily recognized, for on directing the patient to phonate, the two vocal cords which, in a healthy larynx, should approximate each other in the middle of that tube, failed to do so, but remained stationary at the sides of the windpipe. As I could account for the paralysis in no way, there being but a slight amount of inflammatory action in the larynx, and none of the special conditions of hysteria (a frequent cause of loss of voice), and as both the dress and bearing of the party indicated the class to which she belonged, I questioned her regarding syphilis. After a great deal of prevarication it was finally ascertained that about two years previous she had a small sore on the external genitals which had been burned off, and, as she considered, cured. She remembered no secondary eruption. I prepared to follow out the usual plan of treatment in these cases, viz., the local application of electricity by means of the laryngeal electrode, but to my chagrin the battery would not work. I then made some mild astringent application and prescribed the iodide of potash in fifteen-grain doses, thrice daily. I did not see my patient again for five days, when she presented herself in a very happy frame of mind on account of her ability to talk a little. Upon laryngeal inspection a little motion was distinctly visible in the paralyzed bodies. Having obtained the above result solely through the agency of the iodide, I determined, for a time at least, to forego the use of the electricity and see if the voice could not be fully restored by means of the potash alone. I therefore increased the dose to gr. xx., thrice per diem. A week later the potash was again further increased to twenty-five grains, thrice daily. The same plan of treatment was pursued until one hundred and five grains were taken in twenty-four hours, when a retrograde course was instituted on account of the rapid improvement of the patient. The case was a complete success, the voice being perfectly recovered, and the paralyzed bodies restored to their normal condition.

Within the present month I have had at my clinic a case somewhat similar to the one reported above, the paralysis, however, being confined to one vocal cord, the left. The patient is progressing nicely, and the pathological condition gradually disappearing under a course of treatment similar to that tabulated above.

Case II.—*Syphilitic Glossitis.*—This case, one of exceeding rarity, was that of a female, aged about thirty-five years, who attended my clinic at the Metropolitan Hospital. Upon examination the tongue was immensely swollen, so much so that it protruded outside of the mouth. The patient complained of great pain in the organ, together with an inability to swallow any food, either liquid or solid. Along the free border of the gums several points of ulceration were also noticeable.

Upon questioning the sufferer as to the duration of the affection, she replied that she had first noticed the swelling about a week previous, and that it had gradually increased up to the time of her application for treatment. As those of my readers, who have practised in a time when ptyalism was more frequently produced than at the present epoch, may have already inferred, the above case presents all the points of a profuse and injudicious salivation. Upon interrogation, however, it was ascertained that no drugs had been swallowed; a simple gargle of potash, which had been prescribed by a medical gentleman at the commencement of the trouble, being the only medicament employed.

As the patient would not allow the use of the bistoury—a free incision along the dorsum of the tongue on each side of the raphe being indicated to allow of the escape of infiltrated fluid—and as there was a distinct history of syphilis contracted several years before, I ordered her twenty grains of iodide of potash every six hours, and enjoined her to return at the next clinic, two days following. She came at the time specified, declaring that she had faithfully carried out the directions. Upon inspection, the lingual organ had returned to almost its normal calibre, the inflammatory action having nearly subsided. The patient also reported that all pain had disappeared, and that she could swallow liquids and soft food with ease.

Case III.—*Syphilitic Ulceration of Velum accompanied with a Large Perforation.*—This case, that of a man aged about forty years, is an exceedingly instructive one, inasmuch as it illustrates the wonderful reparative power sometimes manifested with reference to the throat in syphilitic patients.

The patient when first examined had all the evidences of tertiary syphilis in the buccal cavity. The entire mucous membrane covering the fauces was greatly congested, the inflammatory redness being of a dusky color, a characteristic peculiar to syphilitic cases, and one that will often enable the expert examiner to instantly diagnose the disease correctly. On the right side of the soft palate, midway between the base of the uvula and the attachment of the velum to the side of the throat, an opening large enough to allow of the passage of an ordinary lead-pencil was distinctly visible. The entire circumference of the above orifice was in an ulcerated condition, and the tissues for at least a line beyond looked as if they were about to become involved in the destructive process. The cause of all this trouble was so apparent that it was hardly necessary to ascertain the patient's preliminary history. In response to the usual questions, the patient replied "that he had contracted chancre twenty years ago, and that he had suffered from pains in the bones for a long time."

The stereotyped course of treatment in a case such as the one portrayed above would be to freely cauterize the edges of the perforation with the stick

of nitrate of silver, and to administer internally the antisyphilitics, mercury and potash, either singly or combined. Now, instead of pursuing this plan, I, following an idea which had been applied by me to several other forms of syphilitic throat troubles, made no local application whatsoever, but simply prescribed the iodide of potash in large doses frequently repeated. The result was most gratifying, for at every attendance of the patient the perforation was smaller, until finally it disappeared altogether, the entire treatment occupying but ten days. There were several physicians who were attending the hospital as students during the treatment of the last-mentioned patient, and who followed up the case in all its stages with great curiosity. They one and all expressed themselves as greatly surprised at the wonderful result produced.

With reference to the throat, there is no doubt in my mind regarding the powers of the system to restore lost tissues, providing the destructive process has not gone too far, and the proper plan of treatment be pursued. I have in several marked instances seen a partially destroyed cord, which had superinduced a great amount of hoarseness, return to its normal condition with a complete restoration of the vocal powers. I have also noticed the same thing repeatedly with reference to some of the adjoining organs.

Case IV.—*Syphilitic Stenosis of the Larynx.*—This case, with which I shall conclude my paper, is by far the most interesting of all. The patient, an adult male of robust appearance, applied for treatment at my clinic on January 3d of the present year. As he walked into the examining-room he presented all the evidences of impaired breathing in a marked degree. The principal symptoms complained of were great difficulty in breathing, orthopnœa, pain referable to the larynx, a feeling of constriction about the throat, and dysphonia. Upon laryngoscopic inspection, the cause of the above peculiar train of symptoms was at once revealed, for a large swelling was seen to occupy the position of the right ventricular band. The other pathological conditions noticeable at the same time were extensive ulceration of the left vocal cord and an intense hyperæmia of the entire laryngeal mucous membrane. Upon inquiry it was ascertained that the trouble had begun with a slight cold, accompanied with hoarseness, about four weeks previous, and that the difficulty in breathing commenced about a week later, and kept gradually getting worse up to the time of his application.

As the robust condition of the patient counter-indicated a phthisical diathesis, the disease was diagnosed as a syphilitic gumma, and the diagnosis was confirmed by the previous history of the case, syphilis having been acquired some twelve years ago. Recognizing the gravity of his condition I prescribed the iodide in twenty-five-grain doses every four hours, and instructed the patient to report to the hospital at any time if the difficulty in breathing should increase. At my succeeding clinic, January 5th, he again presented himself. Upon laryngeal examination the parts looked pathologically the same as on the previous exploration, the gumma having obviously been arrested in its progress. The iodide was now increased to thirty-five grains every four hours, and the same general instructions given as at the previous clinic. January 7th he again appeared, expressing himself as much better. A laryngoscopic investigation revealed the facts that the tumor was much smaller, and that the amount of laryngeal inflammation was much less.

Upon further interrogation the patient averred that his breathing was greatly improved, and that he had slept the preceding night for the first time since the commencement of treatment. After enjoining him to follow out the same plan of medication with great carefulness, I dismissed my patient.

I did not see him again until January 12th, when he came into the examining-room with rapid step and smiling countenance. He reported that he had gradually improved until now, when he experienced no difficulty in breathing, except when rapidly walking or ascending a long flight of stairs. A laryngoscopic examination revealed the fact that the gummatous swelling had nearly all disappeared, together with the surrounding inflammation. The air-tube was also seen to be quite free, whereas at the first examination it was almost completely filled up with the abnormal mass. As it was no longer necessary to keep up the large doses of the iodide, the daily amount was reduced to sixty grains, which he is taking at the time of the present writing.

All the foregoing illustrations form beautiful exemplifications of the wonderful efficacy of iodide of potash in tertiary syphilitic manifestations of the throat.

In the variety of diseases of which Case III. is an example, the general plan of treatment, as hitherto stated, is to freely cauterize the ulcerated surfaces, and administer internally the iodide of potash combined with some one of the preparations of mercury. Now, since the topical application of the solid stick of argentum will not have the slightest effect in arresting syphilitic ulceration, unless the antispecifics are freely imbibed, it seems to me rational to infer that the good effect which is seen to be produced locally, is due, not to the topical application but to the general remedy. I now take a step farther, and state that in my experience it has often appeared that the cauterization of syphilitic ulcerations in the throat retarded instead of hastening resolution. I make this assertion only after repeated experimentation, those patients to whom the iodide was prescribed in conjunction with some mild local application appearing to make more rapid progress. Regarding Case IV., which borders upon the miraculous, and which furnishes the strongest kind of an argument with reference to the powers of the remedy used, it seemed to me so certain that tracheotomy would have to be resorted to, that I had made all preparations to perform the operation at short notice.

A word concerning the manner of using the iodide in tertiary syphilis of the throat, and I will close. If, after a careful examination of the throat, the presence of the syphilitic taint in the system be suspected, even if the patient firmly deny its existence, always give him the benefit of the doubt and prescribe the potash. If the patient be correct in his assertion, the use of the remedy can do no possible harm, while, on the contrary, if the disease is present, the medicine will have a most salutary effect, and your diagnosis be confirmed. Do not wait for the appearance of ulceration before invoking the aid of the antispecific, for mayhap, when you again see your patient, irreparable destruction will have invaded the affected tissues.

The nature and gravity of the manifestations are the sole regulators of the doses to be prescribed. Generally speaking, in cases of simple syphilitic inflammations, unaccompanied with much swelling, ten to fifteen grains thrice per diem will be quite sufficient. If, however, a slight amount of ulceration accompany the inflammatory action, it will be neces-

sary to begin at large doses, say from forty to sixty grains in the twenty-four hours. If the ulceration is marked, and the destruction of a prominent organ, as for instance the velum or vocal cords, be threatened, recourse must be immediately had to larger doses, that is to say, twenty to twenty-five grains should be given every five or six hours. In cases characterized by the rapid swelling of the tissues, especially if the pathological condition be manifested in the larynx—as the instance of stenosis already reported—give maximum doses from the start, as by temporizing you may lose your patient. Generally speaking, if, in a given case of throat disease superinduced by the syphilitic virus, thirty grains of the remedy has been prescribed daily, and the expectant good result has not been produced, the amount should be increased to about forty-five grains, and if this be not sufficient, the augmentation should be kept up until the desired result is obtained. The amount of potash some persons can stand is truly wonderful. I have often prescribed from two to three drachms per day without the slightest untoward result. The only bad effect to be dreaded is a derangement of the stomach necessitating a cessation of the remedy for a short time.

In summing up, I unhesitatingly assert that in the majority of uncomplicated syphilitic troubles of the throat, the internal administration of iodide of potash will invariably be followed by the most gratifying results, provided it be given at the proper time and in the proper doses.

Reports of Hospitals.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

Service of Dr. WM. PEPPER,

professor of clinical medicine.

(Specially reported for The Medical Record.)

A GROUP OF CASES OF FEVER FROM MALARIAL INFLUENCES, WITH REMARKS AND TREATMENT.

Gentlemen: I will bring before you this morning a series of cases of fever which I think will be of practical value.

Case I.—This lad, who resides in the vicinity of Chester, contracted a tertian intermittent fever, which he had about a week before admission. During that time the disease, besides being of a tertian type, presented the condition known as reduplication, that is, two distinct attacks or paroxysms occurred upon the regular fever days.

This is a rare condition, and was not always present in our case, though it occurred during part of his illness. Our patient has had but one regular chill, followed by fever and sweating, since his admission, for he was promptly placed upon the following simple treatment: confinement to bed, simple diet, and twenty-four grains of sulphate of cinchonia in the twenty-four hours, given in four-grain doses, so as to have the effect of eight to ten grains an hour before the expected paroxysm. He may now be pronounced cured.

Case II.—This man has had a rather severe attack of simple remittent fever.

This disease is more common in the hot climates than here, and differs from intermittent fever, as you know, in that there is only a lessening, not a complete cessation, of the fever between the paroxysms. The temperature never drops to normal, but is decidedly more reduced than in either typhoid or typhus fevers.

This reduction is an evidence of its periodical character, which, taken together with the absence of evidences of any local lesions, and the fact that it can be cut short, or at least, controlled by quinine or the preparations of bark, placed it among the malarial affections.

Now, when you have added to this a catarrhal inflammation of the stomach and bile-ducts, you have a bilious remittent fever, which condition is less under the control of the preparations of cinchona.

The case, under the same treatment as our first patient, has rapidly been brought to convalescence, which proves the malarial nature of the affection.

Case III.—This man came into the hospital for treatment for some chronic trouble; but from the first his appearance was so unnaturally dull, listless, and retiring as to attract attention.

At the expiration of three days I found him heavy-eyed, with circumscribed redness of both cheeks and anorexia, and complaining of restlessness at night. I accordingly ordered his temperature taken, which was found to be about 104°. Since then his disease has run the course of a simple continued fever, or rather, more properly speaking, a catarrhal fever, evidently connected with taking cold in his journey to the hospital.

He has had no delirium, epistaxis, purging, tympanites, or eruption—in fact, no characteristic symptoms of typhoid fever.

The temperature, starting in the evening at 104°, fell in the morning to 99°; was up again in the evening to 105½°, down in the morning to 99½°, up in the evening to 102°, then finally down to normal, where it has remained. From this we admit the probable presence of some malarial influence in the case, although, at first, quinine did not break the fever. As there was some irritation of the mucous membrane of the stomach, I enforced a rigid liquid diet and gave also minute doses of nitrate of silver.

As his temperature is normal and tongue slightly coated, I will give him small doses of quinine and treat him in a very simple manner.

Cases IV. and V.—Two brothers, twins, who have been, prior to admission, working in New York, where they were compelled to labor knee-deep in sewer-water.

The first, J., a large, plethoric man, complained of pain in the bones and general malaise. His temperature was 100° which fell to 99½°, then to 99°, then ran up to 102°, finally falling to normal.

He has had, no doubt, a simple malarial condition. His treatment has been twenty-four grains of sulphate of cinchonia daily, rest, and simple diet, which has proved sufficient, as he is now convalescent, with no cough, clean tongue, and appetite fully returned.

The other case—his brother Paul—cannot be considered as doing so well, although he was exposed to exactly the same influences. He has, as you see, a flushed face, dulness of intellect, looseness of bowels, and a temperature which has been fluctuating between 103° or 102½° and 104°. He has had no distinct chill, nor epistaxis, and there is no local disease to explain the present symptoms. His lips are dry, tongue brown, dry, and thick, while his teeth are covered with sordes. The belly is slightly meteoric, hardly tympanitic, but there can be discovered no

eruption on the abdomen, and no enlargement of the liver or spleen.

On examining his urine we found a large quantity of albumen present, with granular tube-casts. This man, therefore, presents the symptoms of a continued fever, together with kidney disease and gastro-intestinal irritation.

Although you have not present here the characteristic symptoms of typhoid fever, you must treat it as such, giving your patient, as you will be so often called upon to do in your private practice, the benefit of any doubt that may exist. I consider the loose, thin stools an important factor, as I do not think they would occur from his present liquid diet without some lesion of the intestines.

I say, therefore, that we must consider it as a case of typhoid fever, complicated, as is shown by the albumen and tube-casts, with acute catarrhal nephritis.

The kidney affection, from the absence of œdema, vomiting, etc., may possibly be considered as only a part of the wide-spread catarrhal condition.

In regard to treatment, this man was placed upon sulphate of cinchonia in the form of suppositories, so as not to add to his gastric irritation, and was given internally small doses of nitrate of silver, opium, and belladonna, as this latter combination has proved valuable in treating this catarrhal condition after the acute state has subsided. In addition, he was of course placed on a liquid diet, consisting of milk, beef, and chicken-tea.

We do not consider the kidney affection in our treatment, except to apply over that region some dry cups, as I am sure that it will gradually disappear with the subsidence of the fever.

From this, gentlemen, you will see different conditions of disease coming from similar conditions of exposure, varying from the mild intermittent to the more severe typhoid. I am not much of a believer in the specific character of typhoid fever, nor do I believe it arises alone from dirt, filth, or putrescence, for this is, to my mind, a far too narrow basis upon which to rest the etiology of so widespread a disease.

These cases should prove to you a great many valuable practical truths, especially this, that it is the exception, not the rule, to meet typical cases of typhoid fever.

It is certainly hard to draw the line at the bedside, however easy it may be in a didactic lecture or in the text-book, for very often do you see this malarial element merging into the catarrhal and typhoid fever.

Ligation of the Internal Iliac Artery for Gluteal Aneurism.—Professor Kasinski has performed this operation successfully for the cure of a moderately large gluteal aneurism. The spray and the antiseptic after-treatment were adopted. According to Kasinski, this operation, up to 1876, was performed four times, of which two cases proved fatal. Stevenson, Atkinson, Mott, and White were the operators. —*Vratch*, No. 47.

Use of Soap-suds in Burns.—Dr. Likernik recommends soap-suds made of any soap on hand to spread over burned surfaces. Their action in relieving pain and reducing inflammation is due to the presence of the alkali, and they possess evident advantages over powdering with bicarbonate of soda.—*Medycyna*, No. 36.

Progress of Medical Science.

Gastrostomy: Establishment of a Gastric Fistula in a Case of Stricture of the Œsophagus.—This case is another illustration of the fact that an opening can be made with safety into the stomach through the abdominal walls. The patient was a male, about sixty years of age, whose family and personal history were remarkably good. He complained of symptoms pointing to obstruction of the œsophagus. When admitted into the hospital not even fluids could be swallowed, any attempt in that direction being followed by their regurgitation. At no time was pain or dyspnœa a feature of the case; apart from the inability to swallow, he complained only of weakness. The œsophageal bougie and probang failed to pass, and stuck about half-way down the œsophagus. Gastrostomy was then performed in the following manner: an incision one and one-half inch in length was made across the linea semilunaris, about an inch below and parallel to the eighth left costal cartilage. The tissues were divided down to the peritoneum, and the cavity of the abdomen opened. The transverse colon was now exposed to view at the lower part of the wound. On the introduction of a pair of forceps in search of the stomach, the anterior wall of that organ was seen on withdrawing the instrument to have been grasped, and the gastric-epiploic artery on the greater curvature, two inches below the part, was seen to be held up. Through the part of the stomach-wall thus brought within the opening, two acupressure-needles were thrust, at a distance of one and one-half inch from each other. Having been passed through the organ, they were again thrust through the wall, and the ends made to rest on opposite sides of the wound. The stomach was now carefully stitched by ten carbolized silk sutures to the edges of the wound, and an incision about an inch in length made through the walls of the organ, between the rows of stitches, with a pair of scissors. A smaller transverse incision was now made, and the resulting corners secured to the lips of the wound in the abdominal wall by stitches. The operation, which had been performed under the spray, now being completed, a large acupressure-needle was pushed through a long india-rubber tube, about three inches from one end. This was then introduced into the stomach, while the extremities of the needle rested on the thoracic and abdominal walls. The tube was fixed in this position by lateral strings. Finally, the long end of the tube was bent downward, and the wound was dressed with antiseptic precautions, drainage being secured by the open tube leading from the stomach. During the three days immediately following the operation the tube was used for drainage purposes, and a small quantity of brownish bilious fluid was collected. Ten days after the operation it was taken out permanently. For a day or two after the operation the patient was fed entirely by enemata of beef-tea and brandy. On the fourth day the drainage function of the tube was changed into a nutritive one, half an ounce of milk and a drachm of brandy being introduced into the stomach. During all this time, although no untoward symptom had occurred, it was evident that emaciation was progressing in spite of the continued enemata and the feeding by the stomach, and on the thirteenth day he died of asthenia. At the post-mortem examination it was found that

there was a small oval tumor encircling the œsophagus about two inches and a half above the cardiac orifice of the stomach. The œsophagus passed through the centre of this swelling and was contracted for an inch of its length, so that a probe was with difficulty passed through it, even after the partial softening of the mucous membrane, which occurs soon after death. The upper orifice of this structure was plugged with a grape-seed, of which the smaller end was downward, so that it was fixed like a stopper in a decanter. The tumor was tough and firm, and its intimate structure was that of epithelial cancer.—*Lancet*, January 1, 1881.

Ligature of the Right Subclavian, Third Division, and the Right Common Carotid, at a Single Operation, for Aortic Aneurism.—In the *American Journal of the Medical Sciences* for January, 1881, Dr. John A. Wyeth has reported an original case, and the condensed histories of seventy-four cases of ligature of the large vessels at the root of the neck, for aortic or innominate aneurism. The conclusions drawn from clinical experience are lengthy and important. The following brief summary will show the relative dangers of distal ligature in the several aneurisms that may occur near the heart. For aneurism involving the aorta alone, eight cases are given. The left carotid was tied in all except two, one of which died. All of the cases in which the ligature was applied to the left carotid "recovered" with "improvement," as did the remaining instance in which the right carotid was tied.

For aneurism involving the innominate and the aorta, the right carotid was tied in five cases (all fatal), and the left carotid in two instances—one fatal, and one recovery with improvement.

For aneurism involving the innominate alone, the right carotid was tied in nine instances, of which six died and three recovered improved (one of these dying "later," from the progress of the disease; another seven months after the operation, from pressure of the aneurism).

For aneurism involving the innominate and one or both of its branches, the right carotid was tied in six instances, of which four died from the direct or indirect result of the operation.

For aneurism involving the carotid alone, the right was tied in five instances, with one death; the left carotid in two instances, with one fatal issue.

Pseudo-Polypi of the Colon; an Anomalous Result of Follicular Ulceration.—This paper, by Surgeon J. J. Woodward, is based upon the study of a specimen with a clinical history, presented to the Army Medical Museum by Dr. John T. Hodgen, of St. Louis. After an acute attack of dysentery the patient suffered for seven months from a chronic alvine flux, and finally died with the usual symptoms of follicular ulceration of the large intestine. As a result of chronic inflammation of the colon, the follicular ulcers had enlarged and adjacent ones coalesced, until for more than nine inches the infiltrated submucosa was laid bare as a raw, granulating surface, on which numerous islets of the thickened mucous membrane remained. Subsequently cicatricial contractions commenced in the infiltrated submucosa, constricting the margins of the islets of mucous membrane, which were further transformed by hyperplastic inflammatory processes, until ultimately they acquired the form of pedunculated excrescences, and projected into the lumen of the intestine like so many polypi. This condition is very clearly distinguished from that still rarer lesion described by Lebert and Luschka, which has received the name of colitis polyposa (Virchow). The appearance of the specimen is well exhibited in several beautiful illustrations taken directly from the specimen, and also in another giving the microscopical structure of one of these false polyps. A photo-relief facsimile of an etching of a somewhat similar specimen described by Menzel ("Acta Medicorum Berolinensium") is appended to the paper.—*American Journal of the Medical Sciences*, January, 1881.

Antipyretic Action of Chronic Nephritis.—That a febrile disease in a patient suffering from chronic nephritis can occur without any elevation of temperature, was noticed some time ago. Dr. Reymond (Vulpian's *Clinique médicale*, Paris, 1879) explained the absence of febrile movement in a case of convulsions, by the fact that the patient suffered from chronic nephritis, which counteracted the tendency of the muscular contractions to produce a rise of temperature. Prof. Botkin, of St. Petersburg, in his lectures advanced the idea that the diseased function of the kidneys leads to the accumulation in the system of substances preventing the occurrence of the febrile state. Dr. Bogojawlensky (Botkin's *Archiv*, vol. iv., p. 235) reported two cases relating to this question. A patient having nephritis was attacked with an exceedingly well-marked croupous pneumonia, but during the third to sixth days his temperature remained normal. Fever appeared at the close of the sixth day, terminating on the next, the critical day of pneumonia. Another nephritic was seized with pleurisy on the left side, and pericarditis with fever of an irregular type. A few days later a phlegmonous inflammation of the axillary glands appeared, extending toward the adjacent tissues; pleurisy and pericarditis became worse, urine diminished and uræmia developed, lasting three days. Despite the formation of an immense abscess and the aggravation of his pleurisy and pericarditis, pyrexia ceased, and the temperature continued normal, with the occasional slight elevations, entirely out of proportion to the extent and intensity of the inflammatory process. In the same volume (p. 306), Dr. Stolnikoff gives the account of the experimental study of this question. He induced chronic inflammation of the kidneys in rabbits by compressing the renal artery, and after the renal lesion existed from one and one-half to three months, he injected into their cranial and thoracic cavities various irritating and septic fluids. He states that, in the animals with diseased kidneys, the temperature was much lower than in healthy animals treated in a like manner, and that at times there was no pyrexia at all.—*Meditz. Obozrenïe*, 1880, xiv., p. 436.

Epidemic Optic Neurosis.—Dr. Reich had an opportunity of observing seventy cases of this disease among the workmen employed, after a heavy snowfall, in clearing a road leading to Tiflis, in the Caucasus. In the mildest cases only more or less marked hyperæmia of the palpebral conjunctiva, lachrymation, photophobia, and pain in the eyes were present. In only three cases of this group he noticed a slight degree of chemosis and of ciliary injection. In the severer forms the patients suffered from intense hyperæmia of the palpebræ, and at times also of the ocular conjunctiva, blepharospasm, photophobia, more or less severe ciliary injection, and even chemosis of the bulbar conjunctiva, the severity of the pain being in proportion to the latter symptoms. Intra-ocular pressure was increased. As a rule the mucous secretion was slight, and in only two or three

cases the typical catarrhal conjunctivitis was present. In 150 men examined he did not find a single case of follicular trachoma or of corneal affection. In darkness only a few could not open their eyes and could readily distinguish the objects; but they still complained of the pain in the eyes. In nearly all the patients the pupils were contracted, and in three cases where atropine (gr. j. to ℥ iij.) was applied no effect was produced. In two cases the pupils were dilated and the ophthalmoscope showed capillary hyperæmia of the optic nerve, with distention of the retinal arteries and veins. The field of vision was diminished. He did not meet with a single case of nictalopia or hemeralopia. The disease developed rapidly, pain in the eyes and photophobia very soon obliging the workmen to abandon their occupation.—*Vratch*, 1880, No. 47.

Gastric Absorption.—The question of the manner of absorption by the stomach is an open one, to decide which Dr. Anrep undertook a series of carefully and ingeniously conducted experiments. After having made a gastric fistula in a dog, he allowed it to recover entirely from the results of the operation. Then he introduced into the pyloric opening of the stomach, and down into the duodenum, an apparatus resembling Barnes' dilator, completely shutting off the cavity of the stomach from the rest of the alimentary canal. He then placed in the stomach a determined quantity of different substances, and after a lapse of time he examined it to see how much of them was left. He found that sugar was absorbed more quickly than anything.—*Vratch*, No. 46.

Cyanosis Due to Chronic Malaria.—Dr. Yazwitzky reports the following interesting case: Private A., during his service in the Caucasus, suffered constantly from malaria. On his return home he had two eclamptic attacks. After the first one he noticed a bluish discoloration about the lips and eyebrows, which extended to a larger area after the second attack. When he came under treatment his skin was flabby, covered with clammy perspiration of a disagreeable odor, and from the forehead to the middle of his trunk it was of a bluish tint, as if stained by a colored fabric, gradually passing into the normal flesh color. Even on the legs, particularly about the knees, the same tint was visible. All the mucous membranes that could be examined—palpebræ and ocular conjunctiva, buccal, nasal and pharyngeal membranes—were of a dark bluish color; even the teeth were bluish. The spleen was also enlarged, and he suffered from periodic malarial symptoms, during which the cyanosis deepened. He was ordered to take quinine, and very soon the symptoms rapidly passed away.—*Meditz. Obozrenie*, xiv., p. 276.

Peculiarities in the Temperature of the Insane.—Dr. Bechteref studied carefully the variations in the temperature of the insane (six cases of atonic, passive, and chronic melancholia, one case of periodical mania, and one case of progressive paralysis), and detected numerous interesting peculiarities. He finds that the temperature of the insane presents a greater range of diurnal fluctuations, even when no physical complications are present, than that of healthy persons. The difference between the morning and evening temperature frequently exceeds 1°. There are distinct successive periods of high and low temperature. The average daily temperature is not constant, and frequently the normal type is entirely reversed, the temperature in the morning being higher than in the evening. In two patients who suffered from pyretic physical disorders this reverse type was retained during the entire intercurrent illness. The writer ascribes these caloric irregularities to the disordered state of the centres regulating the temperature determined by the abnormal conditions of the cranial circulation. According to Landois and Eulenburg, we can readily judge of the state of these centres by the peripheral cutaneous temperature. He instituted a number of observations on healthy and insane subjects with the surface-thermometer, and with the following results: the morning temperature of the skin in the insane is also lower than in the evening, but the diurnal fluctuations are much greater; the peripheral temperature of different regions on the same side, as well as of symmetrical parts, always presented greater differences, frequently reaching 4°, which was never observed in healthy persons. He noticed, also, marked variations in the temperature of both sides of the brain, showing unequal circulation in different cerebral regions.—*Meditz. Obozrenie*, XIII., p. 525.

Symptoms following an Abscess of the Optic Thalamus.—Dr. Rostashinsky had under his care for a number of months a patient complaining of the following symptoms: left hemiplegia; loss of tactile perception; also of the impression of pain, and thermic and electric sensibility on the same side; unconsciousness of the position in which his paralyzed limbs were placed, or which muscles were made to contract by the induced current. There were present, also, temporary vaso-motor disturbances in the paralyzed limbs. On post-mortem examination a circumscribed collection of pus two inches in diameter was found in the depth of the right optic thalamus, at the junction of the middle with the posterior third of the organ. The adjoining parts of the brain were apparently in a healthy state. This case confirms the opinion of those who claim the thalamus opticus to be the centre of muscular sensation, and that the lesions of its internal capsule may produce motor paralysis and anæsthesia without its being the motor centre.—*Vratch. Vedamasti*, No. 440.

Pathology of Hallucinations.—Dr. Kandinsky, having suffered for two years from insanity with hallucinations, indorses the theory of Meynert as regards the origin of hallucinations. He considers them to be the manifestations of an exhausted state of the centres presiding over the mental functions located in the cortex of the anterior lobes of both hemispheres. They never occur with mental delirium, and they fade away with the return of the mental vigor. As a measure to combat them he recommends a judicious mental exercise to an extent which the patient's condition will allow.—*Meditz. Obozrenie*, xiii., p. 815.

Relation of Fetal to Maternal Circulation.—To determine the extent of communication between the two circulatory systems, Dr. Maas injected into the veins of pregnant rabbits different colored pigments and septic fluids. If the blood of the fœtus was examined from one-half to one hour after the injection, he could always detect in it the above granules, with bacteria and micrococci, similar to those introduced into the maternal circulation. But if the examination was made at a later period they could no longer be found in the blood, but were present in the liver and other organs. These facts are thought to explain why the statements of various observers are so contradictory, and, in some cases, negative.—*Przeglad Ckurski*, Nos. 33–35.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 26, 1881.

THE ABOLITION OF THE OFFICE OF CORONER.

We have seen that the proper exercise of the duties of the office of coroner involves the consideration of two essential elements: first, the medical examination, and secondly, the judicial inquiry. It is quite evident that no single individual can perform such duties properly: what would fit an officer for the duties of a medical examiner would disqualify him for those of a purely judicial character. To attain the highest perfection of function in each office requires a special training and a careful education. The coronership, as at present constituted, not only combines both of the important functions in one office, but the incumbents, as a rule, possess no qualifications for either method of examination—in fact, are, as a rule, quite ordinary individuals. To expect from the latter the proper exercise of the duties of coroner is, on general principles, absurd. Nor does it follow that a coroner's jury can either relieve them from responsibility or give character and force to the decisions rendered? The office of coroner being a purely elective one, it can easily be seen that there is no guarantee of fitness for the performance for any of the duties. The principal qualifications would appear to be some acceptable services at the ward primaries, successful manœuvreing in political caucuses, and other acts of disinterested kindness toward the dear people. At all events, the rule is that none but politicians can attain to the honor.

In attempting to reform the present system it is necessary to take into consideration the abolition of the coroner's jury, the division of the office of coroner into two distinct functions, and the creation of a new system of appointment, whereby fitness for the duties will be guaranteed. These are, on their face, reasonable propositions, and are capable of easy fulfilment by the enactment of a suitable law. The passage of such a law could be urged not only on the grounds of general utility, but on the score of economy. It has been proved time and again that the verdict of the coroner's jury has no possible bearing upon the subsequent judicial proceedings—in a word, is useless as a judicial measure, gives no security to the accused, is burdensome upon the citizen, and expensive to the State. The coroner, as an officer, is of no importance, qualified neither for medical nor judicial examinations; he is practically a direct incumbrance to the course of justice. All the valuable part of his services is performed by his deputy, who is the medical examiner. The combination of the duties of two offices into one could be made without any possible loss to the State as to actual service, while the salary of the coroner would be saved. Under the Massachusetts law, the saving to the State in criminal proceedings has been one-third, with the advantage of the services of skilled experts, and the smooth, prompt working of a perfect judicial process. The Massachusetts law is, with slight modification, the model for this State.

The medical inspectors must be appointed to their office by parties who can guarantee their fitness. The mode of appointment is a subject for grave consideration. The success of the Massachusetts plan has been due to the care the governor has taken in making his selections. On general principles it would be safe to assume that appointments could be intrusted to a similar authority in this commonwealth. But the practical difficulty in the way would be the impossibility of vouching for the necessary number of medical men throughout the State. Hence, the suggestion of Mr. Clark Bell, to give the appointment to the county judges is worthy of serious consideration. It appears to us that, taking everything into account, this would be the most satisfactory way of guaranteeing the fitness of every nominee in a given district.

IS THERE AN INHIBITORY THERMIC CENTRE?

An important contribution to the subject of the pathology of fever has been made by Dr. H. C. Wood. Some of the results of this author's studies have been presented before, but the complete work has only lately, by the wise liberality of the Smithsonian Institution, been given to the public. The results of Dr. Wood's studies, taken in connection with previous experiments by Jürgensen, Traube, Liebermeister, Senator, Sanderson, and others, make our knowledge of the essential character of fever, and of the mechanism by which it is produced, a tolerably complete one. And as there is no morbid condition more frequent than fever, or one of which a clear understanding is more necessary, we shall be excused for going into the subject now at considerable length.

The essential feature of fever was announced by Galen, eighteen hundred years ago, to be an abnormal elevation of temperature (*in caloris præternaturam*).

Some recent authorities, among them E. Wagner and Senator, have been inclined to doubt this view, and to believe that an increased tissue-metamorphosis is the primary and essential element. We are inclined to think, however, with Dr. Wood, that this later opinion cannot be sustained. It seems to have been demonstrated that elevations of temperature and the usual accompanying symptoms of fever may be produced without a proportionate increase in the chemical movements of the tissues. On the other hand, by various measures these tissue-changes may be very largely increased without their producing all the characteristic symptoms of fever, *i.e.*, disturbance of circulation, nervous disturbance, and elevation of temperature. The dictum of Galen is apparently confirmed by the exacter researches of the present day, so far as they have yet gone. Still, it must be remembered that abnormal elevations of temperature do occur sometimes without any notable constitutional disturbance. But, accepting the Galenic view as a demonstrated fact, Dr. Wood instituted a long series of carefully conducted experiments, in order to discover whether the production of this elevated temperature is under the control of, or connected in any way with, the nervous system. It is quite generally known, from his previous communications, that the experimenter is a believer in the neurotic origin of fever, but the elaborate and cautiously conducted experiments which have led him to this conclusion are now presented for the first time. We have space for only a brief and partial description of the work performed and results obtained in studying this branch of the subject.

It is to be remembered, in the first place, that heat-production and heat dissipation are the two factors which regulate animal temperature. There may be a fever, *i.e.*, its essential symptom, elevated temperature, when the actual heat-production is less than normal, provided heat-dissipation is also at the same time less. The mechanism which regulates heat-dissipation is generally acknowledged to be the vaso motor system and the nerves controlling the sweat-glands—two nervous agencies which are practically identical. By tetanizing the peripheral blood-vessels the circulation in the skin and the secretion of sweat is lessened. Heat-dissipation is synchronously diminished, and the temperature in the rectum will rise, even though the actual production of heat is less or is unchanged. The nervous mechanism, if there is any, controlling the *production* of heat, is the one, therefore, chiefly to be studied.

It is still very widely believed that this heat-production is also under the control of the vaso-motor system, and is dependent on changes in the circulation brought about by that agency. Dr. Wood cut the spinal cord of dogs, in the cervical region, and found that there was a decrease in heat-production at first, but that this was followed sometimes by increased heat-production. There seemed to be two antagonistic forces at work—one tending to depress, the other to increase heat-production. Destruction of or cutting off the connections of the vaso-motor centre showed that the depression of heat-production was due to the palsy or inaction of that centre. This can be easily understood, since in a complete vaso-motor paralysis the blood everywhere flows more sluggishly, and chemical movements in the tissues must also be less active. Sections were then made at the junction of the pons and medulla. This left the vaso-motor system intact, as was proved by various experiments. But it was found that the sections made in the locality referred to caused an immediate and large increase in heat-production, with a consequent increased heat-dissipation, the latter not being so great as to prevent a rise in the animal temperature. This increase in heat-production was found to be often independent of any change in the blood-pressure or rapidity of the heart-beat.

The experiments so far seemed to show that in separating the medulla from the pons some active inhibiting force, regulating heat-production, was cut off. But, as a large part of animal heat is doubtless produced in the muscular system, and as it has been thought possible that the medullary vaso-motor centre controls chiefly the circulation in the internal organs, the active heat inhibiting force might be only another and a muscular vaso-motor centre, situated higher up. Further elaborate experiments were made to locate this hypothetical centre, if possible. These experiments, which are in part confirmations of the work of other observers, show that destruction of the first cerebral convolution in the dog, posterior to and in the vicinity of the sulcus cruciatus, is followed at once by a very decided increase of heat-production, whilst after irritation of the same nervous tract there is a decided decrease of heat-production.

The influence of this cortical centre, however, is only temporary, and it is not considered likely that its influence over calorification is more than an indirect one. The important point established, however, was that the increased calorification brought about by destroying this centre was not accompanied by changes in arterial pressure; that this portion of the brain had some connection with producing heat, but was in no respect a vaso-motor centre of any kind.

The evidence from all the facts pointed, therefore, to the conclusion that the centre in the medulla dominates the vessels in every part of the body, and consequently that the rise in the heat-production following high section of the medulla, above this centre, is not due to an influence exerted upon the circulation, but directly upon a higher heat-inhibiting centre. This is situated, probably, in the pons.

The first half of Dr. Wood's work ends with this attempt at demonstrating the essential symptom of fever and the existence of a nervous centre concerned

in regulating the production of heat. The remainder of the experiments are devoted to determining whether the rise of temperature in fever is due to increased heat-production or to a retention of heat, and to a further elucidation of the neurotic theory of fever. These latter points we propose to present in a subsequent issue.

THE HARVARD MEDICAL SCHOOL AND REFORMS IN MEDICAL EDUCATION.

The annual report of Harvard University for the year 1881 is extremely interesting to those who care to know what progress is being made in elevating our methods of medical education. The medical department of this university is in a prosperous condition, and has great reason to congratulate itself upon the good work that it has done. The whole number of students in attendance during the three terms of the past year averaged two hundred and fifty-one. An appreciation of the advantages of spending the time of study at the college is shown by the fact that eighty-six per cent. of the graduates in the above year had been in attendance during six collegiate terms. The difference between this condition of things and that in most other medical schools, where two terms is the maximum, is very striking.

The plan of introducing preliminary examinations has had an extremely favorable effect upon the *personnel* of the college. Nearly one-half the students have literary or scientific degrees. The President of the college says, referring to this subject: "It is notorious that medical students have been, as a rule, a rougher class of young men than other professional students of similar age. In this university, until the reformation in 1870–71, the medical students were inferior in bearing, manners, and discipline to the students of other departments; they are now indistinguishable from other students. A corresponding change in the medical profession at large would be effected in twenty years if all the important medical schools in the country should institute a reasonable examination for admission."

The Harvard school is one of the few medical institutions which dares to publish the figures showing the number of students who come up for final examination and the per cent. rejected. The proportion last year was nearly one-third. It is the belief that in one of the largest, if not the largest, college in this city the proportion rejected is about one-fiftieth! —which means that all but a scant half-dozen are rushed through the tests, to the great financial comfort of the college and the shame and damage of the profession.

With the manifest benefits which a system of medical education like that of Harvard confers upon our profession, it is a duty, as well as for its interest, to encourage this particular school and all others conducted on a similar plan.

Reviews and Notices of Books.

A Treatise on the Principles and Practice of Medicine: Designed for the Use of Practitioners and Students of Medicine. By Austin Flint, M.D., Professor of the Principles and Practice of Medicine, etc., in the Bellevue Hospital Medical College, etc. Fifth edition. Philadelphia: H. C. Lea's Son & Co. 8vo, pp. 1,150. 1881.

"Flint's Practice" is recognized to be a standard treatise of high rank upon the principles and the practice of medicine wherever the English language is read. In the present edition we are told that the author's aim was to bring the work up to the level of the existing state of advancement in medical matters, and a careful study of its pages reveals the indisputable fact that in most respects this aim has been reached. The present fifth edition is modified from the fourth by many eliminations, substitutions, and additions. In making the necessary changes the author has "not been influenced by any sense of obligation to maintain consistency of views" with the previous issues of his treatise. Such an explanatory note in the preface was perhaps necessary to allow Dr. Welch the requisite freedom of expression on matters relating to pathology. It is the pathological portion of Flint's work which is most materially altered.

Perhaps it was a wise step on the part of the author to call to his assistance a younger member of the profession, whose studies have been specially directed to morbid anatomy. On the other hand, without extensive personal experience, a discriminating judgment concerning rival claims cannot be had—in pathology even less so than in general medicine. So that Dr. Welch's contributions were in all likelihood accepted without much critical alteration. This was undoubtedly conducive to a harmonious presentation of the subject of pathological anatomy. But, unfortunately, the digest of general and special pathology which he has contributed is somewhat one-sided. It does not fairly represent the weight of opinion on pathological matters, being rather a highly satisfactory *résumé* of Cohnheim's personal views and teachings than the outcome of independent investigation or unbiassed compilation.

This must be apparent to every one who takes the pains to read the book carefully. Nor is any attempt made to conceal the fact, though for obvious reasons it is nowhere explicitly stated. On not a few pages Cohnheim's name appears four and five times. On not a single page can Virchow be found more than twice, unless we have overlooked his name in its third appearance on some page. Rindfleisch, Eberth, Recklinghausen, Samuel Förster, Klebs, Birch-Hirschfeld, Billroth, Cornil and Ranvier, Stricker, Uhle, and Wagner, Weber, Delafield, Buhl, Lücke, Lancereaux, Lebert, Langhaus, Rokitansky, Waldeyer, Zenker, Cruveilhier, Sanderson, Grainger Stewart, Kelsch, and many other more or less prominent pathologists, are all exceedingly *raræ aves*, as compared with the unduly preponderating Cohnheim. Not that the latter is a writer or observer of inferior grade; we would merely remark that a more equable representation as regards personal opinions in pathological questions would not have been detrimental to the value of Flint's new edition. It is not pleasant to be informed in abundant foot-notes

that so and so thinks such and such to be the case, but Cohnheim believes this and this, and Cohnheim is right.

In the next edition of this treatise we hope to find a fuller and more equitable display of pathological luminaries. As regards the clinical histories and treatment of diseases, the portions of the work embracing their description leave nothing to be desired, and in this respect the book is a model of clearness, fairness, comprehensiveness, and good sense. The opinions everywhere reveal the man of extensive experience, diligent study, calm judgment, and unbiassed criticism. The work should be in the hands of every practitioner.

PHOTOGRAPHIC ILLUSTRATIONS OF CUTANEOUS SYPHILIS. By GEORGE HENRY FOX, A.M., M.D. New York: E. B. Treat. 1881.

PARTS iv., v. and vi. contain beautiful examples of the papular and pustular varieties of cutaneous syphilis, with accompanying descriptive text. Each picture is a photograph from life, and is carefully colored by hand.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 24, 1881.

DR. A. E. M. PURDY, PRESIDENT, IN THE CHAIR.

THE paper of the evening was by DR. EMIL NOEGGERATH, and was entitled

ON A NEW METHOD OF PERFORMING OVARIOTOMY.

Having alluded to the remarkable success which of late had attended the operation of ovariotomy in the hands of the best surgeons, and especially since the introduction of antisepsis, he said he believed that even better results would be obtained in the future, and, therefore, that every step directed toward diminishing the dangers of the procedure was to be received with satisfaction. In regard to Listerism, he said that, from what he had seen in his own practice and in that of others, he had come to the conclusion that the more extensively antisepsis was applied, and the more varied was its use in a single case, the greater were the chances of recovery. He therefore considered it the safest policy to disinfect everything surrounding the patient, and, if possible, by different agents.

The plan now in vogue at the Woman's Hospital, of having isolated wards or cottages set apart exclusively for ovariotomy patients during and after the operation, he thought a great advance; but he believed that it was also possible to make a room in a dwelling, or a private room in a hospital, equally salubrious. Having described minutely his manner of preparing the chamber and all the surroundings of the patient so as to guard against the introduction of anything deleterious, he went on to consider the three principal sources of danger in ovariotomy: hemorrhage, shock, and septicæmia.

Regarding the avoidance of the first as a single cause, he had nothing to add to what we knew from the teachings of our ovariotomists. As to shock, it had been proved by G. Wezener's experimental researches, and, later, by observations on the human subject, that the principal element of shock was lowering of temperature, and it could easily be seen how this might occur in an operation like that of ovariotomy, where such a large surface was exposed to evaporation for a very considerable period. Another element in the production of shock was the prolonged contact of the contents of the abdomen with fingers, instruments, etc., and their unavoidable dislocation; a fact also proven by experiments on animals. In addition, there was the influence of narcotism from the anæsthetic, with its paralyzing effect upon the heart, its well-known tendency to lower the temperature of the body, and the injurious effect of vomiting, which added to the mechanical insult offered to the viscera.

As an anæsthetic he preferred chloroform to ether, because in his hands it had proved more efficient in producing complete narcosis, and because he had found that nausea, vomiting, and coughing during and after the operation, were less frequent than when ether was used. He was in the habit of giving bromide of potassium to the patient for two days before the operation, in accordance with the plan proposed many years ago by Dr. Lente; and for the last two years he had added another safeguard, viz., the administration of one or more doses of chloral by the rectum. Since he had been employing bromide of potassium before, and chloral after ovariotomy, vomiting had been an extremely rare occurrence.

Ovariotomists had long been in the habit of performing the operation in a room the air of which was moistened and heated; but, on account of the objections to this mode of applying heat (among which were the depressing influence of an atmosphere loaded with aqueous vapor, the difficulty of maintaining an equable amount of heat around the patient, and the liability to draughts from currents of air entering the room), Dr. Noeggerath had modified the method by applying warmth to the body by placing the patient on a rubber bed filled with water heated to 100° or 102°. One of its great advantages was its effect on the reflex centres of the spinal cord. Experimental researches had shown that abdominal hyperæmia was an essential element and a direct consequence of shock; and we could, therefore, measure to a certain extent the degree of shock which was developed during ovariotomy, by the amount of hyperæmia found inside the abdominal cavity.

His attention had been directed to this point for several years past, and he had observed that, even in operations where the viscera had been exposed more than an hour and a half, the abdominal blood-supply had not apparently been larger than in the normal state, since he had operated with his patients on the hot-water bed. Moreover, in operations which were protracted and very severe from the amount of handling of the pelvic viscera, the color of the face had remained natural, and the pulse large and soft, with only from seventy-two to eighty beats to the minute at the conclusion of the operation.

The third and most important danger connected with ovariotomy consisted in the formation of septic material in the abdominal cavity after the operation, and in order to prevent this Dr. Noeggerath had adopted a different method of operating from that ordinarily employed. His plan was to commence by incising the skin, the subcutaneous layer of fat, and the fascia superfacialis, to the extent of about three inches. Instead of going on incising the tissues down to and through the peritoneum, he plunged the trocar at once into the cyst and emptied it out.

If he found that the liquid was bland he proceeded with the operation; but if it contained pus, decomposed blood, or dark, grumous fluid, he injected through the tube attached to the trocar about half as much of a 2½ per cent. solution of carbolic acid as the fluid measured when removed. This was allowed to remain in the cyst for a while, and then withdrawn. It was done in order to remove the possibility of infecting matter passing from the cyst into the abdominal cavity during the further progress of the operation. After the cyst had been fully emptied, he depressed the handle of the trocar toward the skin below the umbilicus, thus carrying all that section of the tumor which lay below the opening of the trocar against the anterior abdominal wall. Now the uplifted portion of the latter was incised upon the trocar as a guide, down to the cyst-wall, which was lifted up out of the peritoneal cavity by the instrument inside it; after which the pedicle was tied and the cyst removed. The advantages of this procedure over the ordinary method were the following: 1. It simplified the operation considerably, since the search for and separate opening of the serous membrane were entirely done away with, thus removing the principal difficulty connected with that part of the operation which preceded the opening of the cyst itself. 2. The chances of air, instruments, and hands, contaminated with septic material, entering the abdomen, were considerably diminished. 3. The chance of noxious contents of the tumor running into the abdominal cavity is very much less as compared with the ordinary proceeding, and they could be rendered harmless by previous disinfection. 4. The opening in the peritoneum was, on the average, smaller than with the old method, it being adapted in every single instance exactly to the requirements of the case. 5. The shock which resulted from laying open the abdominal cavity was shortened by just so much time as it took to empty out the cyst, the greater part of the operation being reduced to that of simple tapping. There were two contraindications: 1. A preponderance of the solid over the liquid portion of the tumor, or when the whole mass consisted of very small cysts, or semi-solid contents too thick to pass through the canula. 2. A small sac, either originally so, or reduced by previous tapping, on account of the danger of encountering a loop of intestine in front of the cyst. A third possible contraindication might be the presence of ascites; but he had had no occasion to test this question practically. There was this about the procedure, however, that if anything unusual should occur after it had been commenced, it could be interrupted at any step, and the operation finished after the ordinary method.

In ordinary cases he was in the habit of leaving his patients for the following week on the water-bed, which he now filled with cold water as soon as any rise of temperature called for antipyretic measures. He had found it as efficient as Kibbee's cot, and it had the great advantage over the latter of putting less strain on the nurse and causing less disturbance of the patient. If symptoms of nervous depression, or even collapse, were to begin to develop it could be filled again with hot water, and its stimulating effects thus called into action.

The after-treatment properly began at the time when the cyst was being severed from its pedicle, because we had at this moment to decide whether the peritoneal wound (which was the peritoneal cavity) was to be treated as an open wound or to be closed. It was admitted that the question of the treatment of the pedicle was so far settled that in the large majority of instances the intra-peritoneal method was the one to be chosen; but still there remained a certain percentage in which drainage was the only proper treatment. After speaking of the dangers which had hitherto always attended the latter, he said that the only reasonable method of drainage was that proposed and performed with great success by Bardanheuer, of Cologne, which consisted of a modification of Sims' mode of draining through Douglas' cul-de-sac. But, even supposing we had an absolutely reliable method for draining Douglas' cul-de-sac, cases were liable to occur in which even this proceeding would fail. Dr. Noeggerath had, therefore, resorted to a new plan of after-treatment for cases where drainage was indicated, and this consisted in the use of the permanent full bath; the water being allowed to come and remain in contact with the peritoneal cavity. After giving the history of the first case in which it was employed, he described his bath for treating patients after ovariotomy in its now perfect state, and then went on to state that, although it was desirable to have a bath as complete as the one described, it could be very well substituted in a private dwelling by a common movable bath-tub with a double bottom for the reception of hot water; it being only necessary for the purpose desired to employ a bathing arrangement in which the water could be maintained at a certain temperature without the frequent additions of fresh hot water. The number of cases he had treated with the bath was as yet too small to shape any final indications for its use. Already, however, he knew of one contraindication, and within its scope were comprised patients with weakened constitutions, as the drain on the system from loss of serum and fibrine was severe. He proposed to employ the permanent bath as a substitute for ordinary drainage in ovariotomy, and, above all, after Freund's operation, after the removal of fibroid tumors, and after Cæsarean section.

In conclusion, he said that the title given the paper might at first sight appear somewhat presumptuous; but he thought it would be admitted that the principle which governed the several steps of the operation, in the manner described, was entirely new and original, and therefore he believed that he was justified in calling it a new method of performing ovariotomy. Furthermore, he wished the expression "new method" to be applied not to the operation alone, but rather to the combined plan of procedure before, during, and after the operation, including the use of chloral, the hot-water bed, the emptying of the cyst before opening the abdomen, and the use of the permanent bath after the operation.

Dr. T. A. Emmet, on being called upon by the Chair, said that in regard to the first point to be considered in the discussion of Dr. Noeggerath's suggestive paper, viz.: "Is antisepsis altogether necessary?" from the results that had been obtained in Germany and late in Italy, as well as from the experience with it in this country, its great utility could not be questioned. It had become important, however, to determine how far the methods at present employed might be simplified. He would not insist on the use of the spray, but at the same time he was not as yet exactly prepared to do without it. A great many held that in general surgery the spray was not really necessary on account of the thorough and deep drainage which it was possible to get; but as this could not be obtained in ovariotomy, he was of the opinion that it was better to retain the spray for the present at least. As to antisepsis in general, as he had said, there was no question in his mind as

to its very great usefulness. In regard to the point whether antisepsis was possible in private dwellings and in hospitals as well as in the isolated cottages used only for ovariotomy cases, he believed that such a thing was possible, though it would undoubtedly be difficult to carry out properly in all the details. The institution of the system of isolated cottages at the Woman's Hospital had made a wonderful difference in the mortality there. The year before this had been carried into effect there were nine cases of ovariotomy in the hospital, and every one of them had proved fatal. It was true that a defect was afterward discovered in the drainage, but as this trouble was at the other end of the building from that where such patients were kept, he thought it was hardly responsible for the mortality. The first year after the establishment of the cottage system, however, there was a mortality of only three out of thirty-three ovariotomy cases. It was about this time that antisepsis also was first resorted to at the hospital.

As to the question of chloroform *versus* ether, he advocated the latter on general principles, as he believed there was likelihood of its use being followed by shock. His experience with the two anæsthetics had been entirely different from that of Dr. Noeggerath; but at the same time it was only fair to state that he had not employed chloroform for several years now. Dr. Noeggerath's method of puncturing the cyst before opening the peritoneal cavity did not, he said, strike him favorably. If the cyst were single and the fluid were bland and thin, it might be practised very well; but even then there was great danger of doing the patient injury. Adhesions would render the procedure unadvisable, and it was possible that the bladder or other organs might be unconsciously transfixed. In one instance he had found both the stomach and the transverse colon retained directly in front of the ovarian tumor by firm adhesions; and in such a case as that great injury might be done by this method. With proper care he thought that one could guard very effectually against fluid getting into the peritoneal cavity.

As far as the treatment of the pedicle was concerned, he had no doubt that it should be dropped into the peritoneal cavity, after having been properly ligated, although the ligature unquestionably gave rise to trouble sometimes, and it was certainly a matter of interest to know just what became of the ligature. Mr. Keith, who attributed his extraordinary success to the use of the cautery and the great care with which he stopped all oozing, had told him that he lost quite a number of his cases at first, before he acquired that skill which had enabled him to attain a degree of success never reached by any other operator. He also used the drainage-tube more freely than it was customary to do in this country. Personally, however, he did not care to lose a number of patients in learning Keith's plan of operating, and he had not as yet had the courage to adopt it. Taking up the subject of the advantages and disadvantages of drainage, he remarked that it would revolutionize the operation of ovariotomy if perfect drainage could be obtained, but as yet this had been impossible to secure. Even when Sims' method of draining through Douglas' cul-de-sac was resorted to, the amount of drainage was exceedingly limited, and in those cases where we used the drainage-tube the most, viz., where there were adhesions in the pelvis, it was the least applicable. Dr. Noeggerath's plan of draining by means of the warm bath was an idea so new to him that he was not prepared to express any opinion in regard to it; but he certainly thought that it should be given a fair trial, so that it might speak for itself. In the after-treatment he preferred quinine to the application of cold, if there was sepsis present. Cold, however, was very grateful to the patient, and was useful in preventing "wear and tear," though it would not put a stop to peritonitis.

Dr. Garrigues stated that in the city where he came from (Copenhagen), antisepsis was used before any other place, except Edinburgh, it having been introduced into the hospitals in 1869. Before that there had been an enormous mortality in the surgical wards, and this had been entirely overcome by the adoption of Listerism.

In Germany one-half the patients died after ovariotomy, before its introduction, but since then the results had been very favorable. He agreed, therefore, with Drs. Noeggerath and Emmet in regarding antisepsis as essential. It was doubtful, however, whether the spray itself was more beneficial or hurtful. It had the great disadvantage of introducing not only foreign, but often dangerous substances into the peritoneal cavity, especially if carbolic acid was used. Several cases were on record in which the patients seemed to have died of carbolic poisoning. Then, it had the effect of lowering temperature, and, as Dr. Noeggerath had pointed out, lowering of the temperature was one of the principal features of shock. Many of the best surgeons, consequently, now practised Listerism without the use of the spray. Still another objection to the spray was that it was dangerous because it was apt to absorb the attention of the operator and his assistants to such an extent that other important points of the system were neglected. In this manner, instruments which had not been disinfected were liable to be used, while it was much more important that the instruments employed and the hands brought in contact with the tissues should be thoroughly carbolized, than that the spray should be constantly maintained.

Dr. Noeggerath's precautions when operating in private dwellings were most excellent, and he thought it would be a great advantage to carry them out fully. He also agreed with him in regard to chloroform, and was thoroughly in favor of its use in preference to ether. It was true that it was opposed in this part of the United States, but in other parts of the country, as for instance at Baltimore, it was constantly employed. In 1846 chloroform was introduced into Denmark, and since then it had been in exclusive use there, yet only one case of death from it was ever known to have occurred in that country, and he had been in a position to hear of them if other deaths had taken place. The claim for the safety of ether he believed to be exaggerated. Thus, he had heard a well-known surgeon remark that only two deaths from its use had occurred in New York, yet he himself had heard of no less than three fatal cases in New York or the immediate vicinity during the five or six years that he had been living here, and Dr. Emmet said in his book that he had lost half a dozen cases from the administration of ether to individuals suffering from disease of the kidney. This was a very important fact, and the thanks of the profession were due to Dr. Emmet for calling their attention to the matter, particularly since, in these cases, the existence of the kidney trouble was not indicated by the presence of either albumen or casts in the urine. In the prevention of shock, he thought Dr. Noeggerath's plan of employing a hot-water bath was a great advance, and considered the method much preferable to overloading the air with warmth and moisture. Another important point

in preventing shock was to operate as quickly as possible.

As Dr. Emmet had mentioned, there were certain disadvantages connected with puncturing the cyst before opening the peritoneal cavity. In one case in which he saw Dr. Noeggerath operate in this way, the bladder had been pierced by the trocar; but still it might have been necessary to wound the bladder any way. Afterward he saw a case in which Dr. Thomas, in operating in the ordinary manner, had to cut into the bladder. On the whole, however, he confessed that he was not very favorably impressed with the method. In applying cold in the after-treatment, he would decidedly prefer Dr. Noeggerath's plan to the use of the Kibbee cot, since wet cold was very depressing, while this was not the case with dry cold.

Dr. Janvrin believed fully in antisepsis, and said he had had extensive opportunities for observation in the cases of the late Dr. Peaslee and of Dr. Bozeman at the Woman's Hospital, as well as in his own practice. He preferred ether to chloroform, because, as the operation was apt to be a long one, he considered that there was much less danger from shock than if chloroform was used, provided there was no disease of the kidney present. As to the treatment of the pedicle, he had himself made over one hundred ligations, and in only one instance had he ever known a ligature to slip. This was six years ago in a patient of Dr. Peaslee's, and the patient died from internal hemorrhage. The ligature had been tied with great care, but the pedicle was very œdematous, and had, no doubt, retracted. At the present day he always used carbolized silk for ligatures, but he believed that it was never absorbed. Some seemed to think that Dr. Peaslee had claimed that it was, but this was not the case, although he believed that catgut ligatures might be absorbed.

In regard to Dr. Noeggerath's method, the whole thing was new to him, as he had never heard anything of it until this evening. It seemed to him that in many cases it would be admirable, while in others, the nature of which the author had himself pointed out, it would not be applicable. Adhesions, however, he thought, would not constitute an objection, as Dr. Emmet had suggested. The use of the bath also struck him very favorably, and it was nothing more nor less than the carrying to an extreme of the old method of washing out the peritoneal cavity with warm water with sufficient salt dissolved in it to make it approximate serum in character. Provided the patient was strong enough to stand the bath, he believed that it would prove a very excellent procedure. He had had no experience in the employment of drainage through Douglas' cul-de-sac, but the ordinary drainage-tube he had used frequently, and he then related a case illustrating the advantage sometimes to be derived from it.

Dr. William M. Chamberlain thought that Dr. Noeggerath had abundantly sustained the title of his paper by the originality of the various procedures described in it. In regard to the use of the hot-water bed, as well as the bath, he merely wished to suggest that the syphon-principle might, perhaps, be adopted with advantage. Some ten years ago he had read a paper before the Medical Journal Association on the application of the syphon-principle in medicine and surgery, and during the reading of the paper it had occurred to him that by means of it the temperature of the bed and bath described by Dr. Noeggerath might be regulated perfectly.

Dr. Bache Emmet spoke in confirmation of the advantages of the antiseptic system in general, but thought that great care was necessary in order to carry out all its details with success. Thus, in hospitals the dressings used were sometimes old, and if their antiseptic qualities had been to a great extent lost, serious trouble might perhaps arise in consequence. Chloroform, he believed, was more apt to produce vomiting than ether, and, as a rule, he preferred the latter. During the past year ether had been used in 365 cases at the Woman's Hospital, and in no single instance was there any bad result from it. The question of drainage was still *sub judice;* but it seemed to him that if every precaution was carried out in the matter of antisepsis, it ought to be avoided, if possible. If drainage was used, however, he would prefer to have it through the wound rather than make a second opening, since he believed it had been proved, at the time that Sims' method was proposed, that it was impossible to drain all the parts in this way. Like Dr. T. A. Emmet, he preferred quinia to cold where there was a high temperature after the operation.

In bringing the discussion to a close, Dr. Noeggerath remarked that the question of the advantage of the spray in ovariotomy, on the one hand, and in general surgery on the other, had come up several times, and that it was now for the most part admitted that in the latter it would gradually be supplanted by the practice of washing out wounds with carbolic acid solution. In ovariotomy, however, it seemed probable that the spray would be retained. At the Cambridge meeting of the British Medical Association, Mr. Keith had compared ovariotomy to operative procedures involving the pleural cavity. In the latter, if the spray was not employed, the cases did not do well, and the same seemed to be true in regard to ovariotomy. The latest contribution to the efficiency of the spray was a paper by Dr. J. N. Watson, in the *American Journal of the Medical Sciences* for October, 1880, in which he related a series of experiments which he had made. In these it was proved that if the spray was passed over test-tubes while the air was filled with dust, they were disinfected; but if the dust was put in the tubes without the spray, decomposition commenced at once. Like Dr. Emmet, he thought that the operation which he had described was as yet too new to enable one to decide definitely upon its merits; but the disadvantages connected with it he had endeavored to point out so far as they were known to him. In the case referred to by Dr. Garrigues, in which the bladder was punctured, he had afterward concluded that he would have had to cut into it at all events. The bladder here, however, was very much altered in character. In two cases on record the operator had met with this accident unintentionally where the operation was being performed in the ordinary way. As to the liability to injure the stomach, the condition which Dr. Emmet had mentioned was of such extremely rare occurrence as hardly to be considered as a contraindication.

There was undoubtedly a certain amount of danger from the use of the ligature, depending somewhat on the situation it reached. Sometimes it had been known to be passed by the bladder, and sometimes by the intestines, and it was often the cause of inflammation and serious trouble. He was not satisfied in his own mind as to what was the best article for ligatures, but, as a general rule, he preferred silk to silver, on account of the tightness with which it could be tied. The drainage question was one of the most important of the whole; but he thought

that Dr. Bardanheuer had made a great advance toward solving it. Before closing the wound, the latter was in the habit of injecting a solution of carbolic or salicylic acid into the peritoneal cavity, and he then placed the patient almost in a sitting posture, so that from the flanks and higher portions of the pelvis the fluid could reach the cul de-sac. His many successful operations of different sorts had proved that his plan was of enormous value and a very great improvement over the older methods of drainage. When the orifices of his tubes became clogged up with large pieces of fibrinous deposits, it was his practice to employ his carbolic acid injections again. As Dr. Bache Emmet had intimated, it was very important for the best success of the antiseptic system that only fresh dressings should be used, and, consequently, he always took the precaution of carrying such with him to every case in which he operated.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 26, 1881.

Dr. T. E. Satterthwaite, President, in the Chair.

ULCERATIVE ENDOCARDITIS.

Dr. William Osler, of Montreal, Canada, by invitation, read a paper on the above subject, illustrating his remarks by the exhibition of microscopic slides. He distinguished three classes of cases which were clinically known as ulcerative endocarditis :

First.—Those cases in which the disease appeared without any obvious cause, either spontaneously or in connection with rheumatism or some other affection. The term infectious, given by Jaccoud, might be applied to this class. It was the arterial pyemia of Wilkes—the primary ulcerative endocarditis of others.

Second.—Those in which the endocardial disease was secondary to some inflammatory focus—acute necrosis, puerperal endometritis, etc. To these the term septic might be appropriately applied.

Third.—In certain cases of chronic valvular diseases an acute endocardial process might be engrafted (recurrent endocarditis), presenting anatomical appearances similar to the infectious form, but not characterized by the same clinical manifestations, the patients dying with the symptoms of chronic heart disease.

The chief points brought out by the cases he had observed were : 1, that the majority of cases of infectious endocarditis occurred independently of rheumatism ; 2, the frequency with which infectious endocarditis was associated with pneumonia ; 3, the production of acute multiple aneurisms of the aorta in this disease ; and 4, certain histological features in the endocardial vegetations, and particularly a remarkable fungoid growth met with in one instance.

He had also found that the minute bodies found in the endocardial vegetations corresponded in their chemical and microscopical relations to micrococci. They were motionless, highly refractile spherules, less than a micromillimetre in diameter, arranged in groups or colonies without any perceptible stroma. Acids, alkalies, ether and chloroform had no effect upon them.

The question, however, of the relation of the micrococci to the diseases presented many difficulties, and we were probably not yet in a position to give a final answer to the problem. The occurrence of fatal septic cases, closely allied to or identical with those in which a bacteric endocarditis was found, but in which no micrococci could be detected either in the local process or in the blood, taught us that the same poison might exist without the intervention of bacteria. In any case their presence might be only a partial phenomenon in a general infective process.

On motion of Dr. Alonzo Clark a vote of thanks was tendered to Dr. Osler for his communication.

Dr. Alonzo Clark, then remarked that in some respects he agreed with Dr. Osler. The difficulty which presented itself to his mind, however, was that the micro-organisms were supposed to enter the circulation from without. The question was—could a minute body possess sufficient inherent force to overcome blood-pressure, and thus enter the vessels? Of course, formed particles within the vascular channels might easily get out. But he questioned whether the opposite was known to take place. Moreover, most recorded cases of this variety of endocarditis involved exclusively or mainly the left heart. Why should this be? If the micrococci entered the veins of the body, they ought to be found in the right heart as often as, or even more frequently than, in the left. Again, it must be asked, had such germs intrinsic septic power, or were they to be regarded merely as the carriers of the poison?

He pointed out that, in the rare cases involving the right heart, abscess of the lung had been observed. The experiments of Virchow with the injection of indifferent solid particles had resulted in the production of pulmonary stasis or embolism, but special inflammatory symptoms or metastatic abscesses had not occurred. Then it was well known that, in several instances in which minute organisms had been supposed to cause mischief in the body, they had been collected and allowed to multiply by cultivation. Had the doctor taken any steps in this direction?

Dr. Osler answered that his experiments in cultivation had invariably produced negative results.

Dr. Clark resumed, that in view of this fact, the questionable collections might be held to represent only some form of fibrin. Incrusted tubercle also would appear minutely granular. He had subjected such old tubercular deposits to the action of chemicals, and had found that while some would yield to ether and dissolve in dilute acids producing effervescence, others would resist even the action of strong acids. He questioned whether boiling and the influence of such reagents would not have power to destroy any granular collections of a vegetable nature.

Dr. Osler said that the difficulty suggested by Dr. Clark had also occurred to him. These bodies resisted almost too strongly to be classed with vegetable products, since other vegetations did not show a similar pertinacity. Nor did he wish to commit himself by positive assertions. His position was one of neutrality. It was further evident that those germs did not produce the characteristic features of the disease, because these symptoms had been observed without micro-organisms. A case in point was described. All such observations militated against the idea that these particles were the real *materies morbi*, and favored the notion that they were merely concomitants of disease. Klebs and his followers thought the germs entered the system through the intestinal or respiratory surface.

Dr. Satterthwaite asked how these collections behaved when the specimens containing them were stained with hæmatoxylin.

Dr. Osler answered that they took the tint, after the manner of all such germs.

Dr. Howe thought that it was hardly fair to class

cases involving double fractures or other extensive injuries, and followed perhaps by osteomyelitis, under the head of infectious endocarditis. The same objection also applied to cases in which meningitis of traumatic origin, or surgical pneumonia, were present, as in the second group mentioned by the doctor.

Dr. Osler replied that he wished to be understood as limiting the term infectious endocarditis to those cases in which the disease manifested itself without obvious cause. The cases alluded to by Dr. Howe would come under the head of ulcerative endocarditis following injury. As regarded the case in which meningitis was found, this affection was ascertained to be of non-traumatic origin, being a pia arachnitis such as occurred idiopathically. Allusion was here made to a case of similar nature, seen in conjunction with Dr. Peabody, at the New York Hospital.

Dr. Peabody stated that in the case just referred to there was no cranial fracture to account for the development of the meningitis. The post-mortem examination, however, revealed the presence of septic particles within the blood-vessels, especially those of the lungs, where colonies of micrococci were found to exist.

Dr. Heinemann observed that the granular masses would become stained when submitted to the influence of proper reagents.

Dr. Satterthwaite asked whether the infectious form of endocarditis was not identical with the diphtheritic endocarditis of German writers.

Dr. Osler replied in the affirmative, adding that the affection had received various names, and was also known in German literature as mycosis endocardii.

Dr. Satterthwaite remarked that the term diphtheritic, as applied to this form of endocarditis, was an unfortunate one, because the disease rarely appeared in conjunction with diphtheria. He agreed with Dr. Osler in regard to the nature of the bacteritic organisms, for he too was unable to see in them the cause of disease. Many such deposits unquestionably had a post-mortem origin, and even after death they might get into the vessels, fill the tubes of the kidney, etc. With reference to Dr. Osler's specimens, he was of the opinion that they showed true micrococci, such as he had seen in preparations sent here by Prof. Eberth. But that was no reason why these bodies should not have entered the tissues after death. In this connection he alluded to the recent experiments made by Wood and Formad *National Board of Health Bull.*, Suppl. No. 7), who had found abundant low organisms a few minutes after death, in animals which during life were entirely free from bacteria. Nevertheless, such bodies might also be present during life in certain cases. With regard to Klebs, that observer had in a measure retracted his steps in reference to germ theories. He had found that cross-sections through the minute rods would produce the impression of spherules; hence, the latter had been oftener seen than the former.

ABSCESS OF LEFT FRONTAL LOBE OF CEREBRUM.

Dr. E. C. Seguin presented a specimen of the above, which he said was interesting with reference both to its pathogenesis and to localization. He gave the following account of the case:

On April 11, 1880, I was asked to see a case in consultation. The patient was a young married woman, aged about twenty-eight years, who had formerly enjoyed good health and had borne several children. During the month of February one of these children had died after a severe illness, and she had undergone considerable fatigue. She seemed depressed, weak, and anæmic afterward.

About four weeks before the date of the consultation she complained of pain over the left eye. This was soon accompanied by pain and exophthalmus, and on March 24th Dr. Knapp was called in and diagnosticated orbital (sub-periosteal) abscess. This was opened on March 26th by Dr. Knapp.

It was remarked that the pus was under great tension, and that it spurted out a considerable distance when released. Pain ceased at once, the exophthalmus disappeared, and the wound quickly healed. During the first few days of April all seemed going on well; the wound was healed; the patient was free from pain; she was taking tonics, and on the 3d made a call on a near neighbor.

During the night of April 3d and 4th, one week before my examination, she awoke with severe headache and vomiting; ever since she has lain abed, presenting the following symptoms: headache, chiefly mastoid and through the base of the skull; occasional vomiting; irregular respiration; irregular and very slow pulse, varying from sixty to fifty beats per minute; stupor and general feebleness. As negative points there were no symptoms about the eyes, objective or subjective, except a partial ptosis of the left upper lid (which had been incised); no fever, chills, convulsions, paralysis, aphasia; at no time had there been coma. The urine was free from albumen. The patient was soporose, but could be roused by loud speaking; she answered questions as if half asleep, but in such a way as to leave no doubt as to the preservation of language. She put up both hands to the mastoid regions when indicating the seat of pain. A minute inspection showed no paralysis except about the left eye, whose upper lid drooped and whose internal rectus was inert. The pupil on the left site was not fully dilated, but it was a little wider than the right. The optic nerves appeared somewhat congested, and were dim at their periphery, but there was no actual choking. Patient appeared to feel pinching well everywhere. The thermometer showed no fever. The pulse varied from fifty-three to sixty-six beats per minute, and it was a reluctant, delusively full pulse, with no real strength. The breathing was easy and regular, but friends of the patient described quite well a Cheyne-Stokes breathing which they had observed. There was neither redness nor tenderness about the site of the orbital abscess.

I diagnosticated an abscess of the brain probably in the left frontal lobe, and expressed the opinion that the patient was in imminent danger. She died the next day in a comatose state, no new symptom having been observed.

It was then learned that for two years Mrs. F—— had suffered from frequent attacks of headache, lasting several hours. The pain was frontal, and sometimes extended along the nose and into the left temple. There had never been symptoms of chronic nasal catarrh.

The autopsy was made on April 13th, about thirty hours *post-mortem*. We found a large abscess the size of an English walnut in the left frontal lobe. It lay wholly under the cortex cerebri, in the convolutions of the orbital lobule and in the second frontal convolution. Viewing the hemisphere from the side, the apparent posterior limit of the abscess was the anterior border of the lower part of the third frontal gyrus. The external connections and origin of the abscess were most interesting. There was

only one point of adherence between the diseased frontal lobe and the dura mater, and that was over the orbital plate of the frontal bone, immediately under the swollen frontal lobe. There the dura mater was thickened and adherent to the pia mater and cortex cerebri, forming the inferior wall of the abscess, over a space as large as a ten-cent piece (about 15 mm.). Under this patch of pachymeningitis the orbital plate of the frontal bone was necrosed and perforated; a probe was easily passed into the orbit.

In the orbit, under its periosteum, pus was found, and a part of the roof and the inner wall of the orbit were carious. Careful dissection by Dr. H. Knapp showed disease of a similar kind in the ethmoidal cells and frontal sinus. I need say nothing more of the conditions of these parts and of the pathology of the orbital abscess, as the case has been fully reported from this point of view by Dr. Knapp.

The appearance of the necrosed orbital plate, and of the thickened, adherent dura mater, was precisely similar to what I have several times seen in cases of suppurative disease of the internal ear, with cerebral abscess by contiguity. The genesis of the abscess must have been alike in the two situations.

In December, the brain having been sufficiently hardened in bichromate of potash solution, I imbedded it in Gudden's microtome, and made several horizontal sections through the whole brain with the view of demonstrating the relations of the abscess. These cuts showed that the abscess was of quite as large a size as at first supposed, almost perfectly globular in shape, measuring about 38 mm. in diameter. It contained ordinary pus, and was lined by a distinct membrane 1 to 2 mm. thick. The anterior, inferior, and external limits of the abscess were thinned cortex and pia mater, and superiorly, posteriorly, and internally, it was bounded by apparently normal white substance. The whole of the white centre of the frontal lobe, except a portion near the convexity of the hemisphere, was destroyed to within 10 mm. of the folds of the island of Reil, and about 8 mm. of the head of the nucleus caudatus. The mass of white substance connecting the posterior part of the third frontal convolution, and the anterior gyri of the island of Reil, with the internal capsule, were uninjured.

This last fact is of capital importance in estimating the bearing of this case upon the current notions of cerebral localization.

The above description of the topography of the lesion, especially its posterior limitation, is made from the surface exposed by the lowest cut made, viz., one passing through the speech-centre of Broca, about 10 mm. above the apparent commencement of the fissure of Sylvius (pia still adherent). The rest of the brain was healthy to the naked eye.

This remarkable case seems to me of much importance as a negative contribution to cerebral localization. It is in exact accord with recent experimental data, and with the *post-mortem* findings of the last ten years, that an abscess placed like this one should give rise to no motor symptoms, and should not cause aphasia. It is wholly within what are now called the unexcitable districts of the brain. The only symptoms present were the partial paralysis of the left third nerve (more immediately caused by the orbital abscess?) and signs of intracranial pressure. Yet it is important to note that in spite of the enormous pressure which must have existed, there was no actual neuro-retinitis.

I have elsewhere reported another case of (smaller) abscess in precisely the same location (left frontal lobe), in which no symptoms referable to this lesion were present.*

On the other hand, numerous autopsies are on record in which a smaller lesion (softening, hemorrhage, etc.) placed a centimetre farther back in the left frontal lobe, involving the posterior part of the third frontal gyrus or the band of white substance between it and the nucleus caudatus, has given rise to severe symptoms, hemiplegia, or aphasia, singly or combined.

Dr. Ripley thought that, as a general rule, slowly progressive invasion was less likely to produce symptoms than one more rapid.

Dr. Seguin observed that this would largely depend upon the seat of the lesion. If the central region were involved, gradual invasion would certainly produce early symptoms.

Dr. Knapp stated with regard to the pus here found in the orbit and frontal sinus, that abscess of the latter region was but little known. Nevertheless, the frontal sinus not infrequently became the seat of retention-cysts, owing to its communication with the ethmoidal cells, or from the presence of polypi. But, as a rule, in such cases, the abscess would point at the inner aspect of the orbit. In the present instance, however, the abscess had pointed externally, and it was this circumstance which had misled many who saw the case to make an erroneous diagnosis. Such purulent collections might also simulate periostitis. In the present case there existed an extension of the orbital plate, forming an outward prolongation, and it was for this reason that the abscess had formed at the outer part, and not at the usual inner upper angle of the orbit. Primarily there had evidently been a retention in the frontal sinus; subsequently extensive caries was developed.

Dr. Seguin remarked that the consideration of this case had again suggested to him the propriety of surgical interference in similar instances, especially if the existing conditions so clearly pointed out the location of the abscess. It was to be remembered that the frontal lobes bore injuries well, being essentially unexcitable. He thought the life of this woman, who was otherwise enjoying perfect health, might have been saved by trephining, followed by evacuation of the pus.

Dr. Knapp stated that he, for one, would be willing to practice incision from the orbit in cases so clearly marked as the present one. He added that the orbit might be removed without incurring serious risks.

Dr. Seguin asked whether that would be as desirable a locality as the frontal region.

Dr. Knapp answered that it would be, if anything, better, on account of its being at a lower level, which would facilitate drainage.

Dr. Satterthwaite asked whether he would not prefer drainage through the frontal sinus?

Dr. Knapp replied in the negative.

Dr. Heineman alluded to Prof. Detmold's case, which was one of the first on record of trephining for cerebral abscess.

Dr. Howe remembered several cases, in one of which the patient had recovered after the operation.

Dr. Satterthwaite instanced a further case which he had seen at the New York Hospital, but which had terminated fatally.

* A Contribution to the Study of Localized Cerebral Lesions. Transactions of the American Neurological Association, vol. ii., pp. 122-124, New York, 1877.

RUPTURE OF THE KIDNEY FOLLOWING INJURY.

Dr. Heineman showed a specimen of ruptured kidney, in which the organ was almost completely severed, being held together only by a bridge of connective tissue at the renal pelvis. The specimen was removed from the body of a man who had sustained a fall from a height of fifteen feet, thus receiving a sternal fracture and the above renal injury.

Dr. Peabody had seen several cases of this kind, but in no instance had the rupture been so complete.

DIVERTICULUM OF SMALL INTESTINE SHOWING TYPHOID FEVER LESIONS.

Dr. Heinemann presented a second specimen, which was taken from the body of a patient who had died of typhoid fever. In the small intestine a diverticulum was found, and on examination it was seen to exhibit the characteristic ulcers of typhoid fever.

Dr. Peabody said that about two years ago he had found a similar diverticulum. The peculiar feature of his case was that there had been an attempt at formation of a special mesentery for this pouch. In this way a bridle was developed, and the man died of intestinal obstruction due to this cause.

Dr. Howe remarked that he had recently seen an intestinal diverticulum, about three inches long, in a case of strangulated hernia at the St. Francis' Hospital.

CAVITY OF LUNG COMMUNICATING WITH BRANCH OF PULMONARY ARTERY AND BRONCHIOLE.

Dr. Peabody presented a specimen consisting of the right lung of a patient who had died from the results of hæmoptysis. The man was twenty-six years of age, and had complained of dyspnœa, with cough and occasional bloody expectoration. An examination of his chest revealed subcrepitant râles, but no marked dulness. Slight bronchial breathing was heard over the base of the right lung. Profuse hemorrhage suddenly came on, the blood gushed into the trachea, and the man died.

At the autopsy, in addition to widespread bronchitis and peribronchitis, a cavity was found in the lower lobe of the right lung. It was about the size of a hen's egg, and leading into it there were found a rather large branch of the pulmonary artery and a bronchial tube. The mouth of the vessel was closed by a recent clot.

Dr. Peabody also exhibited a heart showing marked hypertrophy of the left ventricle, without the presence of any valvular lesion. The hypertrophy was found to accompany a condition of chronic diffuse nephritis.

OSTEOMA OF FRONTAL SINUS.

Dr. Knapp presented a specimen of the above, and gave the history of the patient from whom it had been successfully removed. The case has been fully reported elsewhere.

Dr. Knapp also briefly referred to another case in which surgical interference had resulted in death. In this instance the tumor extended into the cranial cavity.

Dr. Seguin remarked that this case went to support his position with regard to the inexcitability of the frontal lobes, for in Dr. Knapp's last case special paralytic symptoms had at no time been observed.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 3, 1881.

Fordyce Barker, M.D., LL.D., President, in the Chair.

Dr. R. Beverly Cole, of San Francisco, and Dr. John P. Gray, of Utica, were introduced to the Academy, and invited to occupy seats upon the platform.

The Statistical Secretary, Dr. F. V. White, announced the death of the following Fellows: Jacob A. Van Houten, M.D., Wm. C. W. Glazier, M.D., Robert D. Nesmith, M.D., and James Otis Pond, M.D.

The President spoke of the twenty-eight years of continuous and faithful service performed by Dr. Pond as Treasurer of the Academy, and appointed Dr. John G. Adams to prepare a memoir.

UTERINE HYDATIDS.

Dr. Wm. T. Lusk exhibited a specimen of uterine hydatids, and made some remarks concerning the pathology, the diagnosis, the prognosis, and the treatment of this form of degeneration. In this case, as in nearly all reported, it was supposed the condition was that of placenta prævia, and, indeed, it was chiefly with reference to the latter condition that differential diagnosis was to be made. The points relied upon by Dr. Lusk were: first, the size of the uterus does not correspond to the supposed period of gestation; second, after the sixth month most of the signs of pregnancy may exist, but there is absence of fetal movements and sounds of the fetal heart. In such a case only one of two conditions could exist: either the uterus was occupied by a dead fœtus or by hydatids, and usually the distinction could be made out by the general feel of the uterine tumor.

THE PRESIDENT'S INAUGURAL ADDRESS.

The President then delivered his inaugural address, in which he expressed his warm appreciation of the honor which he had received with such unanimity, and of the confidence expressed that the functions of the office will be performed with impartiality, zeal, and conscientious fidelity. All of his predecessors in office then living were present, and he was sure they all would concur with him in the statement that no one before him had been so lucky in the time of his service—a time in which circumstances had combined to make what reputation the position gave easily won. The fruit of years of zealous labor by his predecessors and other untiring, honest workers for the Academy, was ripe and ready for the harvest.

The President then gave a brief sketch of the career of the Academy from the time when, thirty-four years ago, all of the best men in the profession united in its organization for the purpose of the cultivation of the science of medicine, the advancement of the character and honor of the profession, the elevation of the standard of medical education, and the promotion of the public health, to the time when "we have our agreeable, convenient, well-lighted, and perfectly ventilated library-hall, which is a monument more enduring than brass or marble to keep the name of Abram Du Bois ever present in the memory of coming generations of the profession, and a legacy of the stamp of nobility for his descendants." The library now contains over 17,000 volumes, exclusive of pamphlets, and is daily increasing.

THE SCIENTIFIC WORK AND THE MEDICAL PRESS.

The scientific work of the Academy during the last two years had been of the most satisfactory character,

and he paid a special compliment to the medical press of this city for the painstaking and faithful presentation of that work to the profession. The President also expressed the hope that soon the Academy would devise some plan whereby it can publish all its papers and discussions at short intervals. He made special reference to the great value of the *Index Medicus*, and bespoke for it a most liberal professional support. Dr. Barker then spoke of the influence which the Academy had exerted upon

THE PUBLIC HEALTH,

and said:

"One of the avowed objects of the Academy is the promotion of public health, and it has earned in the past a right to recognition as the fountain-head of whatever excellence New York may boast as to sanitary regulations. To the Academy New York is indebted for the existence of its protecting Board of Health. It set in motion the efficient board that did the great work in stamping out the cholera; a work which saved untold lives to the State. This offspring of the Academy has inspired most of the legislation upon hygiene ever since, reforming our buildings, giving us improved sewerage, checking the adulteration of food, and especially punishing those who have destroyed unnumbered children with adulterated milk. If the public of this great commonwealth could only be made to appreciate the great pecuniary loss which is due to the violation of sanitary laws, it would be roused to most efficient action for its protection. Notwithstanding the fact that New York is more favorably situated than any other large city in the North or in Europe for the best sanitary conditions, its rate of mortality is in excess of others. A large part of this excess in our death-rate is undoubtedly due to causes which could and should be controlled by municipal regulations, and thus the lives of 6,000 persons might annually be saved. The pecuniary loss to this city from these causes can with difficulty be estimated, but it is safe to say that it amounts to many millions of dollars annually. The loss to Philadelphia, from the ravages of small-pox in 1871 and 1872, has been estimated by competent statisticians at nearly $20,000,000. The pecuniary loss to this city the present year from diphtheria, scarlet fever, typhoid fever, pneumonia, and other diseases generated by preventable causes, such as defective plumbing, bad sewerage, filthy streets, and a poisoned atmosphere, beyond all question would exceed our city debt and reduce our taxation, if it could have been saved and applied to this purpose.

"A few weeks ago I had the pleasure of perusing a paper entitled 'What the State Owes the People; Public Health is Public Wealth,' which was read before the American Public Health Association at its meeting in New Orleans, La., in December last. It struck me that it would be wise to borrow the plan of religious propagandists, and publish the paper as a tract. Such information is needed. I have found the error very prevalent among our citizens that the dangers which arise from the public neglect of sanitary laws are chiefly confined to the poorer classes and those living in crowded tenement-houses. All, however, agree that it is a burning reproach to the civilization of the age, and a still greater stigma upon our governing authorities, that the avarice of a few hundreds should be permitted to make miserable, unhappy, and, as I absolutely know in some cases, positively ill, hundreds of thousands of our population, by establishing manufactories in our suburbs which fill our atmosphere with noisome, offensive, and unhealthy influences. The truth is that, in some respects, the peril to which those who are able to live in the most comfortable and even luxurious circumstances is greater than those of the poorer classes. The danger to which all of us are exposed, despite such precautions as most take, is infinitely greater than that from assassins and desperate burglars.

"Medical men, who have a good professional reputation, have great power in moulding public opinion on all subjects on which they are expected to be better informed than the average man. On all these matters which I have just been describing they ought to be able to influence legislation. I believe that I am warranted in asserting that the Fellows of the Academy of Medicine are in sympathy with the purposes of the New York Sanitary Reform Society, and are most anxious to give it all the aid in their power. I am sure that every one of us feels the importance of an improvement in tenement-houses as regards an adequate supply of air and light, and the prevention of defective and dangerous plumbing, the abatement of nuisances which afflict public health, such as those at Hunter's Point, and to secure the supervision of the Board of Health over the plumbing of all buildings hereafter erected in this city. Bills designed to attain these various ends are now before the Legislature, and intelligent, zealous action on the part of the profession in instructing those whom they know among its honorable members, may contribute essentially to secure their passage."

With reference to

THE ACADEMY,

the President remarked that "within the last eighteen months $18,000 have been subscribed and paid by members for building its hall and the improvement of its library. The value of the property now belonging to us, as represented by its hall, its equipments, and its library, was appraised last year at $81,430. On this there is a mortgage of $10,000, which constitutes the whole debt of the Academy. Its income from annual dues of its members and admission fees from new members is sufficient for its current expenses, although the interest on the mortgage would have left only a small surplus for keeping up the library, in the purchase of books and for appropriations for binding the journals, had it not been for the generous gift of Mrs. John Jacob Astor."

With reference to

THE PROFESSION

in this city, he doubted whether, in any former age, the medical profession had been held in so high esteem, and whether in any other city in the world it had held so high a position socially, or was, on the whole, better remunerated for its labor than in New York. "Many of our wealthy people do not content themselves by paying the bills sent to them, but often add a most generous honorarium. We should not expect such generous avowals of our services, but we should aim to deserve them. We can see very clearly how largely the community is indebted to the profession; let us be careful not to forget what we owe to the community."

There has been a great change in the profession within the last thirty years, and while it should not be said that mistakes had been made by opposing errors, it might be said that they had been made in our methods of opposing them. Errors kindly exposed, and spurious doctrines treated with a wise charity at the hands of a liberal profession, would soon cease to have an existence.

On motion by Dr. Gouverneur M. Smith, the Academy tendered a vote of thanks to the President, and requested him to place at the disposal of the Council a copy of his address for early publication.

Brief addresses were then made by Drs. Willard Parker, Austin Flint, S. S. Purple, Beverly Cole, of San Francisco, and John P. Gray, of Utica.

The bearer of "The Loving Cup" was then followed by the President, the ex-Presidents, the officers, the guests, and the Fellows of the Academy to the basement, where a bountiful collation was served.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 13, 1881, *to February* 19, 1881.

Baily, E. I., Lieut.-Col. and Surgeon. The leave of absence granted him December 30, 1880, from A. G. O., extended one month. S. O., 35, A. G. O., February 11, 1881.

Gibson, J. R., Major and Surgeon. To accompany Battery A (Light) and Battery D, 2d Artillery, from Fort McHenry, Md., to the U. S. Barracks, Washington, D. C., for temporary duty thereat. S. O. 26, Department of the East, February 11, 1881.

Elbrey, F. W., Capt. and Asst. Surgeon. Relieved from duty at Fort Bayard, N. M., and assigned to duty at Fort Union, N. M., relieving Asst. Surgeon Kane. S. O. 31, Department of the Missouri, February 12, 1881.

Bryne, C. B., Capt. and Asst. Surgeon. To accompany Battery C, 2d Artillery, from Fort Johnston, N. C.—abandoned—to Washington, D. C., and then proceed to Fort Barrancas, Florida, and report to the commanding officer of that post for duty. S. O. 11, Department of the South, February 11, 1881.

Hoff, J. V. R., Capt. and Asst. Surgeon. To accompany the four batteries of artillery from Fort Monroe, Va., as medical officer to Washington, D. C. S. O. 27, Department of the East, February 11, 1881.

Finley, J. A., Capt. and Asst. Surgeon. To accompany the Battalion, 3d Artillery, from New York Harbor, as medical officer to the U. S. Barracks, Washington, D. C. S. O. 27, Department of East, February 11, 1881.

Kane, J. J., 1st Lieut. and Asst. Surgeon. When relieved by Asst. Surgeon Elbrey, to proceed to, and report for duty at Fort Bayard, N. M. S. O. 31, C. S., Department of Missouri.

Medical Items and News.

Distribution of the Hospital Fund.—The subcommittee of the Distributing Committee of the Hospital Saturday and Sunday Association, appointed recently to prepare a plan for the distribution of the $22,617.15 collected on Hospital Saturday and Sunday, reported yesterday in favor of the following schedule, which was adopted: Institution for the Relief of the Ruptured and Crippled, $2,000; Mount Sinai Hospital, $6,000; German Hospital, $3,000; Presbyterian Hospital, $2,000; House of Rest for Consumptives, $2,000; Hahnemann Hospital, $2,000; Home for Incurables, $1,500; New York Infirmary for Women and Children, $1,000; New York Eye and Ear Infirmary, $500; Orthopedic Hospital, $500; Women's Hospital, $1,000; Ophthalmic Hospital, $500; Manhattan Eye and Ear Infirmary, $617.15. Total, $22,617.15.

Improved Dover's Powder.—Dr. Isaac W. Chisholm, New Concord, Ohio, writes: "Permit me to state, in reply to Dr. S. Mitchell, Jr., of Hornellsville, N. Y., in regard to 'improved Dover's powder,' which he published in Medical Record, February 12, 1881, that I recommended the substitution of the bromide of potassium to the old sulphate in the *Ohio Medical Recorder*, Columbus, Ohio (see March number, 1880, page 473), and was afterward copied into *New Idea*, giving me *due credit*. The gentleman may not have seen it. I have been using it for a number of years—in fact I use no other, considering it *far superior* to the old sulphate."

Coroners and Calomel.—At a quarterly meeting of the Westchester County Medical Society, in Mount Vernon, February 15th, the case of Dr. P. R. H. Sawyer, of Bedford Village, who had been censured by the coroner's jury in the case of the late John W. Williams, of Poundridge, whose body had been exhumed last fall owing to suspicions that he had been poisoned, was taken up for consideration. Dr. George H. Magness, of White Plains, to whom a small portion of the intestines had been submitted for analysis, testified before the coroner's inquest that he had found a grain and a half of corrosive sublimate, and that the membranes were very much perforated by the poison. It also came out in the evidence before the coroner that Dr. Sawyer had given Williams, who was a confirmed inebriate, "twenty grains of calomel for a first dose, and left twenty grains more to be taken in four hours; also, a large dose of compound cathartic and four blue pills." It was believed that that large quantity of calomel had, by mixing with the hydrochloric acid in the stomach, formed the corrosive sublimate found, and which Dr. Magness thought sufficient to cause death. Dr. Sawyer, who is a member of the society, reported the case to that body and demanded an examination. Dr. Magness is not a member of the society. The society endeavored to get a copy of the testimony taken at the coroner's inquest, but the coroner said he did not have it in his possession, having lent it. Both the disputing doctors made their statements before the society at the meeting referred to. After a hearing and discussion, the society passed a set of resolutions in which it censured the coroner for not having in his possession and not having filed in the County Clerk's office the testimony taken at the inquest; secondly, it censured the coroner's jury in having found their verdict "censuring" Dr. Sawyer in his treatment of the case upon the evidence; and, thirdly, it exonerated Dr. Sawyer from any malpractice in the case and approved his treatment, which they considered entirely professional. These resolutions were passed with but one dissenting voice, that of Dr. Augustus Van Cortlandt, of New Rochelle, who considered the prescription given above enough to kill any man, and branded the whole action of the society as a "whitewashing arrangement." The question now arises, since poison was found in Williams's stomach, how did it get there? Did the doctor's dose of calomel produce it, or was he poisoned, or did he commit suicide? Whatever answer be given to these questions, we consider that the case shows the necessity of abolishing or changing our present system of coroner's juries.

Legislation Against Bogus Medical Colleges.—A law has just been enacted by the Ohio Legislature making it a criminal offence to buy or sell or use a fraudulent medical diploma, *i.e.*, one not issued from a chartered medical college, to persons who have regularly studied medicine for the usual length of time.

Legacies to the City Hospitals.—The late Augustus F. Miller, a broker of this city, who died last January, left in his will $4,000 for the German Hospital and $5,000 for St. Luke's Hospital. The will is, however, now being contested by his alleged widow.

The Change in By-laws of the Medical Society of the State of New York.—Dr. Wm. Manlius Smith, Secretary of Medical Society of State of New York, writes as follows: "I have just received the Medical Record of February 12, 1881, and of course turned at first to the report of the late annual meeting of the State Society. It strikes me as an unusually full and *correct* report. There is, however, one error of such a character that it needs correction or it may lead persons interested astray. It is in the second column of the 194th page, at the commencement of 'New By-Laws,' which, by the way should be 'New By-Law.' The first line of this paragraph, and part of the first line up to and including 'and,' should be omitted. The by-law should begin with: 'Permanent members of the age of sixty years and upwards,' etc. The error doubtless arose from the reporter taking from the piece of paper on which I wrote out the by-law, a line or two which I had written as commencing the by-law, and then abandoned as not expressing what was intended. I left a space, and then wrote out the by-law as it was adopted. The reporter has got the abortion and the full-grown fœtus mixed into a monstrous birth.

"Please see the error corrected in the next issue of the Record, or I shall have lots of applications from permanent members of ten years' standing who are not sixty years of age."

New Medical Schools.—Two new medical schools, one regular and one eclectic, have recently been organized in St. Louis.

A Death from Ether has occurred at Jefferson College Hospital, Philadelphia. The patient, a woman, aged twenty-six years, was a patient of Dr. J. R. Levis, who was to operate upon her for fibrous anchylosis of the hip. She had taken ether previously without ill effects, and her viscera were all healthy. She took between two and three ounces of ether, and the operation was safely performed. She did not rally from the anæsthetic, however, and in spite of stimulants, an hour and a half after etherization commenced, she died. Post-mortem revealed nothing abnormal. Shock may have had something to do with the fatal result.

Governor Long, of Massachusetts, in his inaugural address, recommends the building of less costly asylums for the increasing number of the insane; he also recommends such classifications of them, and such freedom from restraint and increased medical care as has been constantly advocated in the Record. Public opinion is gradually shaping itself to the more enlightened views, and proper legislation will surely follow in time.

Professor Huxley has been appointed to the position of Inspector of Fisheries, left vacant by the death of Mr. Frank Buckland, M.R.C.S.

Peptone in Pus.—Peptone, which was formerly thought to be exclusively the product of digestion, has recently been found by Hoffmeister in pus. He found it first in the pus of empyema. It exists in the corpuscles only, and is in the proportion of gr. v. to gr. xv. per ℥ j. of pus.

Failure of the Anti-Vivisection Bill.—Mr. Bergh's bill to prohibit experiments on animals, which was introduced into the New York Legislature during the present session, and referred in both branches to the Committee on Public Health, was reported adversely on the 18th instant by the Assembly Committee, and the report agreed to by the Assembly. This finishes the business, we presume, for the present session. The bill was the same with that introduced last year, and which met with a similar fate in the Committee on Judiciary.

The Quarantine Establishment.—The State Senate has passed a resolution offered by Mr. Jacobs, calling on the Quarantine Commissioners to inform the Senate within ten days what amount of money had been expended by the commission since the date of the last appropriation, with detailed items of the same; also, what money was now due and owing by the commission; also, whether, in its opinion, the Quarantine establishment should not be made self-sustaining by appropriating a portion of the large fees now accruing to the Health Officer of the Port to the maintenance of the same, without injustice to that officer.

In the subsequent discussion it was shown that during the past year from $75,000 to $100,000 in fees went into the pocket of the health officer. Yet last summer $5,000 of the State's money was spent in repairing the house in which the health officer lives and pays no rent.

The Death of Dr. Andrew Wood, M.D., LL.D., Edin. and Cantab, etc., occurred on January 25th, at the age of sixty-nine years. The deceased was a member of the General Medical Council, and had for a long time been prominently connected with the cause of medical education. Dr. Wood was noted for his work in general as well as in medical literature. He made excellent translations of Horace and of several of Schiller's poems. He had continued his practice up to the day of his death, which occurred suddenly from rupture of a valve in the left ventricle.

The Catgut Ligature.—The absolute value of the catgut ligature has not yet been established, and some recent experiments of Dr. G. F. Arnaud, recounted in a memoir entitled "Contribution à l'Etude de la Ligature dans le Traitement des Anévrismes," have especial interest. Dr. Arnaud ligatured the carotid or femoral artery of dogs fourteen times with carbolized catgut, and examined the parts from four to sixteen days afterward. In nine cases the ligature had entirely disappeared; in two it was partially absorbed; in three it was little altered. In twelve cases the inner coat of the artery was not cut at all. In twelve the middle and inner coats were divided. The clot, when not absorbed, was very small, and the obliteration of the artery was complete and firm. Arnaud concludes that the action of catgut is like that of hemp, with the important exception that the outer coat of the artery is not ulcerated. The fact that catgut is absorbed is corroborated by these experiments.

British Geography.—The *Lancet* announces the death of Dr. David P. Smith, Professor in the Yale Medical School, and one of the most distinguished surgeons in the State of New York.

Chian Turpentine takes a new lease of life from a successful case under its use reported in the *Lancet* by Dr. H. A. Allbutt.

Clothes for Night-Calls.—An English physician has invented a suit of clothes for use in night-calls. He can dress himself completely in it within a minute and a half. If a person sleep in his shoes the time of dressing can be reduced to thirty seconds.

The late Thomas Carlyle, in his "Sartor Resartus," made some suggestions in regard to this matter. He observes: "The simplest costume which I anywhere find alluded to in history, is that used as regimental by Bolivar's cavalry in the late Colombian wars. A square blanket, twelve feet diagonal, is provided. In the centre a slit is effected eighteen inches long; through this the mother-naked trooper introduces his head and neck, and so rides, shielded from all weather, and in battle from many strokes (for he rolls it about his left arm); and not only dressed but harnessed and draperied.

"With which picture," says the author, "of a state of nature, affecting by its singularity and old Roman contempt of the superfluous, we shall quit this part of our subject."

We do not know enough of the details of our English inventor's dress to say whether he has simply seized upon the "Colombian idea" or not.

The Electric Properties of Dried Collodion are said by Dr. Seure to be very great. It is negatively electric to gutta-percha and sulphide of copper. If the outside of a bottle be covered with dried collodion and then rubbed, small sparks can be easily obtained. Dr. Seure thinks that some therapeutic effects may be obtained from the substance, and suggests that collodionized silk be worn by hemianæsthetic subjects.

High Potencies.—At the recent meeting of the New York State Homœopathic Society, Dr. H. M. Paine had the candor and boldness to say: "Our experience in the use of high potencies is based, as Hahnemann's was, on theoretical gronnds only. It is one of the most singular forms of idealism ever seriously entertained by the medical profession. I firmly believe that when our reputed cures are reported in connection with all cases treated we shall find that their frequency is not greater than those of daily occurrence, without medicine of any kind."

Priapus Redivivus.—Any one walking along Broadway just now may see at intervals some miserable-looking wretches parading aloft a placard with the following announcement: "Use Damiana Bitters. Extract of Damiana, the Great Aphrodisiac and Stimulant to the Sexual Organs of both Sexes, etc.!" The creatures carrying this very bestial advertisement crowd their way among the ladies on the sidewalks up town, as well as among the men down town. We might suppose that the days of the Bacchantes and of the processions to Priapus had been revived. It is certainly humiliating to think that such a flagrant appeal to sensuality and transparent device of the brothel-keeper should be tolerated by our authorities, the more so since damiana has but rarely and incompletely the powers ascribed to it. It will often help a flabby bladder, but is no aphrodisiac, according to the experience of most of those who have used it.

A Monument will be erected in memory of the Russian surgeons who died during the war with Turkey.

The Leprosy of the Bible, according to Dr. Geo. E. Post, of Beirut, is not the elephantiasis Græcorum of the present day, but was a form of *lepra* (now generally called *psoriasis*). In a condensed statement of his views in the *S. S. World*, Prof. Post says: "Lev. 13 and 14 are the chief authorities on that subject. If any one will take the trouble to follow the descriptions of the rise, spread, and decline of the malady as there given, he will see that the essence of it is a white or lurid or gleaming spot, producing more or less baldness in places covered with hair, often arising from a boil. Now, in point of fact, the *aleppo button*, which is in appearance much like a boil, and which lasts for many months—often for a year or more, so that the Arabs call it *Habbat es Sinj, the year boil*—is frequently followed by a tetter or lepra, a spreading scabby eruption, following much the course described in Lev. 13: 18–23. As these often occur in the face, they greatly disfigure their unfortunate victims by eating away a portion of the nose or cheek or lip, or by leaving an unsightly scab, and after years a lurid contracted cicatrix. The same disease—*lepra*—occurs from other causes. It is a malady having some tendency to wear itself out and get well. This is in accord also with the description of the disease of the Bible. By simply waiting, the unfortunate unclean often become clean. No modern leper ever wore out his malady.

"On the other hand, none of the well-known signs and appearances of the greater leprosy are described in Lev. 13 and 14.

"The writer is aware that the adoption of this view would take away the force of innumerable commentaries and fine poetic allusions to the deadly elephantiasis of the Oriental lepers. But it will not in any way diminish the force and point of the ceremonial distinctions in regard to leprosy. *Lepra vulgaris*, especially the spreading chronic form of it, is a more visible and disgusting disease than elephantiasis, very intractable, and suitable as a legal and ceremonial illustration of moral uncleanness, incurable by ordinary medicinal means, loathsome to the beholder, and impairing the usefulness of those parts of the body which are attacked."

A Government Investigation of the Causes of Insanity.—Mr. Morton, of New York, introduced in the House, on Feb. 14th, a bill directing the National Board of Health to make a thorough investigation into the causes of insanity in the United States and the methods of treatment practised in the several States and to submit a report to the next Congress, giving the result of their investigations, with any recommendations which may seem well adapted to prevent an increase of insanity and to secure its better treatment.

Mr. Lister has been elected President of the London Clinical Society.

THE PREVENTION OF LACERATION OF THE PERINEUM.

By H. G. LANDIS, A.M., M.D.,

PROFESSOR OF OBSTETRICS, ETC., IN STARLING MEDICAL COLLEGE, COLUMBUS, OHIO.*

According to Tacitus, the ancient Germans punished some offences in a conspicuous manner; hanging the culprit on a tree; others they buried in mud, desiring to hide even the mention of the crime. For some mysterious reason, the laceration of the female perineum in labor seems to have been placed by the profession in the list of disgraceful occurrences which are not to be investigated nor acknowledged as existing. The subject is seldom brought before a medical society, that some one does not arise, and with owl-like gravity declare that he has no *personal* experience with the accident, has not met with it in twenty years' practice, and so on; as though some moral turpitude was involved in witnessing a laceration, or as though we have such perfect knowledge of the means of prevention that its occurrence reflected upon the skill of the practitioner. But as a matter of fact it is very frequent, occurring in the practice of the skilled and unskilled. I speak, of course, of all degrees of laceration, slight as well as great, for even a small rent is undesirable, and to be prevented if possible. For myself I freely confess that I have witnessed it in successive cases to a disgusting extent, and again a season of immunity would prevail, when every perineum escaped scatheless, and this, too, no matter what was done or left undone. I find, also, from this strange professional reticence, that it is difficult to obtain either statistics or well-grounded opinions as to the value of any of the methods which have been from time to time recommended for the prevention of this accident; and that every one is forced to rely almost exclusively upon his own experience or to accept the enthusiastic statements of those who have invented methods and are noisy in their advocacy. It is to urge upon the profession a more careful study of methods and more readiness to communicate results that I make these remarks, having no new views to champion and few facts to declare. I will not detain this learned body with any elementary statements as to the structure of the perineum or the nature and effects of the laceration, but will briefly submit the following propositions as to the physiology of the perineal stage in labor, with a running commentary:

1. The perineum is the seat of a secondary force in labor, due to its inherent elasticity, by which the direction of motion of the child's head is changed after passing through the pelvis. That is to say: the uterine force impels the head toward the coccyx, or as reflected by the curved walls of the pelvis upon the posterior segment of the perineum. The elastic resistance of the perineum pushes back the head; but not exactly back, but more toward the symphysis pubis. Hence the head moves in the resultant of the two forces and glides over instead of through the perineum. This fact is the key to the mechanism of the act, and its knowledge essential to any study of the subject.

2. If the uterine contractions are too strong to be resisted by the perineum, the latter gives way and the head does not move upward but directly onward and through the perineum. The matter of strength is relative, for a perineum strong enough to resist some uterine contractions may be lacerated by others.

3. The ability to resist the uterine force depends upon the degree of inherent elasticity in the perineum, which is a variable factor and is influenced by several circumstances. Thus, a large head, which greatly distends the perineum, impairs its elasticity directly as compared with a smaller head. Or the same head, if extended so as to present with its occipito-frontal circumference, will be larger than when it presents well flexed, with its cervico-bregmatic circumference. Again, if the second stage of labor is long delayed and the circulation in the perineum thereby impaired, it may become sodden and elastic. Also, during pregnancy the perineum becomes developed to about double its former bulk. This development may fail to take place, and there seems at times to be a congenital deficiency or malformation of the perineum. A too straight sacrum may also result in bringing the head so posteriorly upon the perineum that it is necessarily taken at an advantage and torn. These and other circumstances must all be taken into consideration in observing the ability of a given perineum to resist the strain put upon it or the influence of methods designed to assist its strength.

4. A distinction must be made between the resisting force-supplying capacity of the perineum and its capacity for stretching without giving way; in other words, between its elasticity and its mobility, or rather cohesive properties. Thus it may happen that a perineum is capable of being stretched to an extent fully admitting the passage of a large head, and yet has so slight a power of elastic resistance that it does not repel the head, and therefore does not furnish the secondary force needed for its advance and delivery. It stretches, but only stretches; and the mere stretching of the perineum cannot advance the head in the proper direction, since the uterine force cannot act around a corner unless there is something to deflect it. In such a case the uterine force drives the head against the perineum, which readily yields until the vulvar outlet is amply sufficient to allow the head to pass; but there being no elastic resistance to oppose it the uterine force continues to impel the head in the only direction in which it is capable of acting, until the perineum can no longer dilate and its substance is torn. What is needed is not a more *distensible* perineum, for distention is generously provided for, but the artificial replacement of the missing secondary force, which should change the direction of the uterine force and propel the head over instead of through the perineum.

5. A perineum which, either from imperfect development, congenital defect, recent infiltration, or any other cause, is incapable of stretching sufficiently to admit of the passage of a given head, cannot be prevented from laceration by any method. Episiotomy may determine the point of laceration—a doubtful good—but if there is no "stretch" in the perineum it must be torn or the head cannot be delivered. There are, then, cases in which no method will prevent the accident, and it is a step in advance if this fact is clearly recognized. The next step would be to be able to recognize the condition in each case, and thus know fully the necessary limitations of our science. There remain cases, no doubt the majority, in which the disposition to dilate is ample, but in which the elastic resistance is too feeble to combat the uterine force, and in which, after the fullest dila-

* Read before the Franklin County and Central Ohio Medical Societies and published at their request.

tation requisite for delivery, the unresisted uterine force drives the head through the perineum to a greater or less extent. It is also to be recognized that the shoulders, etc., are subject to the same conditions, but I speak of the head only and in a generic sense. The prevention of laceration should therefore be sought in a method which will supply the secondary force when absent or abnormally deficient. To which we must add another clause, viz., that the method employed shall not itself do mischief; otherwise we need scarcely look further for the method which is on theoretical grounds to be preferred, than to one of the oldest methods—the direct support of the perineum by the opposed hand. For in this venerable custom we practically replace the perineum by the hand. When the uterine force advances the head the hand presses it back again, or, as Miller recommends, also somewhat forward toward the pubes, and thus the head is properly directed; but while we are doing this we are also subjecting the perineum to a cross-fire. The head from above is forcing its particles asunder, and the hand from without is doing the same thing from the opposite direction, and so from foes within and foes without the perineum is very apt to come to grief. Absolute abstinence from any attempt to save the perineum is better than an indiscriminate resort to this in every case. The able paper published by Dr. Goodell in the *American Journal of Medical Sciences* for January, 1871, so effectually disposes of this that I have no doubt the practice is largely abandoned. The method recommended by Dr. Goodell is the application of a method spoken of by Ould and Smellie for the extrication of the head rather than for any care of the perineum. The original statement by Ould, as given in a note to Smellie (Sydenham edition), is as follows: "When the child is very near coming into the world, with the top of its head just at the labia pudendi, and that there is no obstacle to its expulsion but either the weakness of the mother, the size and inflexibility of the cranium, or the dryness of the parts, the fore-finger must be well greased and introduced into the anus with the back of the hand toward the sacrum. When it is thrust in as far as may be, by bending you will easily fix it under the child's jaw-bone, near its articulation with the cranium; thus the mother's efforts may be very much assisted by pulling the child forward with the finger bent under the jaw." Goodell more specifically directs us to seize the head between two fingers in the rectum applied over the child's face, and the thumb placed in the vulva upon its occiput. With this grip we may assist or retard the advance of the head, regulate its degree of flexion or extension, and guide it in the proper direction. Other incidental advantages are claimed for it not necessary to detail at this time. Notwithstanding the theoretical advantages of this method there will be little hazard in asserting that others as well as myself have seen a laceration occur while faithfully employing it. The hold which we have upon the head is too slippery and uncertain to enable us to guide it during a powerful contraction of the uterus, nor do I find that the other hand can render much assistance at such a juncture. What we cannot do with our fingers may be perfectly achieved by the obstetric forceps. With them we have it in our power to determine when and how far the head shall advance, and in what direction, which is all that can be asked, and I know of nothing so likely to save a doubtful perineum as the skilful use of the forceps. The objections to the forceps are, that the risk of laceration alone hardly justifies their use, and that their unskilful use will cause instead of prevent the accident. The first objection is a practical one, for in many rapid labors we have no time, nor could we gain assent for their application. There remain many cases of first labor in which a long perineal stage furnishes ample time and excuse for their employment. The second objection must be left to the conscience of the individual, and applies as well to all important resources in medicine.

In a limited number of cases I have found the veritable method of Ould very useful, not only for the purpose recommended by him, the extrication of the head, but also for the protection of the perineum. And not exactly his method unless, as is probable, he deviated from it in practice, since it is often difficult as well as unnecessary, to place the fingers under the child's chin—instead of placing them over the forehead or malar bones—which is the better procedure. Thus, when the head distends the perineum so that at the end of a pain the head is not retracted, but remains at its furthest point of advance, hugged against the subpubic arch and making the perineum bulge considerably, the head may usually be at once pressed through the vulva by the fingers in the rectum without any fear of rupturing the perineum. And why? Because the uterine force is not driving the head against the perineum, but the fingers alone are propelling it in exactly the right direction, so that *the perineum is only called upon to stretch and not to resist into the bargain*. The philosophy of this manœuvre is at the bottom of any sound method of prevention, namely, to bring the head over the perineum during the absence of the uterine contraction. For it is the uterus which ruptures the perineum much oftener than the size of the head—a result often due to the conjoined impatience of the woman and physician. The one is in a hurry to be delivered, the other is tired and anxious to escape from an irksome attendance, and while the woman bears down vigorously the physician does not discourage her efforts, but, at most, vainly attempts to resist the tremendous uterine force with the pressure of his fingers.

I am convinced that a mistake in theory, and consequently in practice, is contained in the supposition that the *suddenness* with which the perineum is made to dilate is the important factor in laceration. We hear much more of the necessity of preparation and gradual dilatation than of the powerful disruptive efforts of the uterus. There is, no doubt, some truth in this view, but it is greatly exaggerated. Too many women are delivered in ten minutes, after full dilatation of the os uteri without harm to the perineum from the rapid descent, to make the minority a rule. In many women one pain brings the head from the superior strait to the perineum, and the next brings it into the world. The perineum is undergoing a preparation for distention throughout the entire labor, and, as Goodell suggests, is even actively dilating before the head approaches it. When the head begins to press upon the perineum its tonicity is directly impaired by every degree of continuance of the labor. The longer the head takes to distend the perineum the more its circulation is impeded and its powers of cohesion diminished. What is needed is not less suddenness of dilatation but less powerful and disproportionate uterine contractions. Such a case as this which I saw recently is common enough. A young primipara had been long in labor, and the head was beginning to press feebly upon the perineum. The vulvar opening was so small that there was scarcely

room for the introduction of the second blade of the forceps. The head was made to distend the perineum fairly as soon as the instrument was applied, and allowed to retract. This was repeated four or five times, at intervals of a minute or so, when a very large head was withdrawn over an entirely unscathed perineum. The experience of all will enable them to judge whether the hour or more which would have been required for the natural delivery in this case, would have been safer for the perineum than this comparatively rapid dilatation and delivery. I do not, therefore, see that anything is gained by the mere prolongation of the perineal stage of labor by arresting the progress of the head until the perineum is supposed to be ready for the end. It may indirectly be prolonged by the prohibition of bearing down efforts, since a considerable amount of force may be needed for dilatation. In the cases where the accident is presumably due to an inherent defect in the perineal structure, we would seem to have no resource, and it is important to recognize this condition before the value of any method can be exactly determined. There is one kind of perineum which I think I have seen often enough to recognize and describe. Its appearance when the head begins to press upon it is as follows: About a finger's-breadth in the median line, extending from vulva to anus, is smooth tissue and quite thin, while on either side of this the perineum is thick, elevated, looking not unlike the labia majora on a small scale, and with a rather rough cutaneous covering. The median strip appears to be the only dilatable part of the perineum, and in spite of all precautions more or less of a tear occurs as the head escapes. As I have noticed it only in primiparæ, I had inferred that it was a congenital or developmental defect in the structure, the lateral thickening being probably due to adipose deposit. Among the methods I have tried, and about abandoned as futile, is one which may be of little service in such cases. The ball of the thumb is pressed upon one of the nates, and the skin, etc., is crowded over toward the perineum, while the fingers reaching across, pull the skin of the opposite buttock in a similar direction. In this way we crowd skin and cellular tissue into the perineum and afford a larger distensible surface. We cannot increase the size of the perineal body or muscles, but by increasing the thickness of the cutaneous covering may add a little strength to the whole structure.

A New Departure in the Treatment of Purulent Ophthalmia is described in the *American Practitioner* by its London correspondent. It consists in the application to the entire conjunctival surface of an ointment of one grain of the nitric oxide of mercury, one-fifth of a grain of sulphate of atropia, and one drachm of vaseline. When the ointment is applied, the patient lies down, and, if restless, is put under the influence of an anæsthetic (chloroform is used but nitrous oxide will answer better). Next, the eye being well cleansed from discharge with tepid water, with a large camel's-hair brush, the ointment is freely pushed beneath the upper and then the lower eyelid, so as to touch the entire surface of the conjunctiva. As long as the eyelids are swollen this operation is repeated three times each day, but when the eyelids open freely, one application daily suffices until the cessation of the discharge. Mr. Bader, author of this treatment, says that it has had the best results, both in children and adults. It is especially successful when adopted at the outset of the disease.

FALLACIES OF PHYSIOLOGICAL EXPERIMENTATION REGARDING ATROPIA.

By THOMAS W. POOLE, M.D.,

LINDSAY, ONT., CANADA.

In Dr. Ringer's excellent "Therapeutics," fifth American edition, p. 462, we read: "Atropia excites the cord, and heightens reflex action; an effect long undetected till it was pointed out by Dr. Fraser, for the paralyzation of the motor nerves prevented the drug's action on the cord displaying itself on the muscles; but if the motor nerves of an extremity are protected, by ligature of its blood-vessels, from the paralyzing action of the atropia, then its stimulating action on the cord manifests itself in the protected leg. The afferent nerves are unaffected by atropia."

It is here asserted:

First.—That the spinal cord and its motor nerve-trunks may be, and are, in directly opposite conditions of functional excitation at the same time and by the action of the same drug.

Second.—That these motor nerves are more influenced by peripheral blood-supply (although the sheaths of nerve-fibrils are not penetrated by blood-vessels) than they are influenced by their proper nervous centres in the cord, and that the nerves require to be protected peripherally, in order to be influenced from their centres in the cord.

Third.—It is also asserted that in the final stage of atropia-poisoning the tetanic convulsions then witnessed are evidences that the nervous centres are undergoing the exhilaration of increased stimulation, and even in the very act of dying are discharging their proper functions of generating nerve-force with extraordinary vigor.

It is only in the entire absence of any rational explanation of the phenomena of this state that ideas so preposterous could have been entertained or tolerated.

The "stimulating action on the cord" and the "heightened reflex action" here mentioned, as the effect of atropia, are held to be indicated by the passing of the limb into tetanus, as will presently appear from the report of the experiment. But what is such an inference worth in the face of the fact that in the hands of Prof. Stannius ligaturing the vessels of the extremity (as in the experiment mentioned by Dr. Ringer) produced a similar tetanus of the muscles without the employment of the atropia at all (Dr. C. B. Radcliffe's "Lectures," etc., pp. 85–94). It is by overlooking just such sources of fallacy as is here indicated that professedly scientific experiments are brought into contempt.

I have not before me the details of Dr. Fraser's experiments, but Dr. Isaac Ott, in his "Action of Medicines," furnishes an abridgment of them, from which the following is quoted entire:

"*Experiment.*—Four-fifths of a grain of sulphate of atropia was injected with eight minims of distilled water into the abdominal cavity of a frog weighing four hundred and fifty-three grains. In eight minutes its movements were sluggish, and some weakness occurred in the anterior extremities. In six hours *the nerve-paralysis was more complete;* stimulation did not excite any reflex movement, and even galvanic excitation of an exposed sciatic nerve failed to produce any muscular contraction, although the muscles themselves readily contracted [through the action of the current on the unpoisoned intramuscular terminal

nerves]. Sixty-eight hours after the dose a change of position had occurred; the anterior extremities were flexed, and formed an arch-like prop, on which the raised head and thorax were supported. On the fifth day tetanic attacks supervened, and lasted in all seventeen days" (p. 52).

The other experiments quoted by Dr. Ott do not differ from this one in any notable particular except that the procedure is varied to illustrate the special action of atropia on the cord alone. In the experiment quoted in full from Dr. Ott it will be noticed that the stage of motor nerve *paralysis* was prolonged till between the second and third day, or, if it be preferred, we will say till the fifth day, when tetanus began to show itself strongly. We are expected to believe that the *paralysis* then gave way to a still longer term of nervous *excitation;* this being the alleged condition of the cord during the final stage of tetanic spasm, and up to the last moments of life. During all this time the frog was slowly dying, and had the theory of the day not required that its spinal cord should be acting with undue functional vigor, surely such a supposition would have been deemed incredible. There are men who scoff at "mere theory," but here is a practical illustration of how a mere hypothesis, entirely unproven and incapable of proof, can influence conclusions which leave their mark upon all future time.

Dr. Ott assures the reader that "this experiment demonstrates that atropia in small doses paralyzes and then convulses," which might as well read "paralyzes and then excites." In a subsequent experiment he refers to atropia as "a paralyzer and spinal stimulant," and points out that in the case of small doses the stage of stimulation follows that of paralysis, but where the dose is large, both occur together. He writes: "Now the theory is that the *paralytic and spinal stimulant actions coexist* in frogs after the administration of large doses of atropia" (p. 54). Further on in the same work, while treating of belladonna, he states: "It paralyzes the motor nerves of frogs at the same time that it excites the spinal cord; after they recover from the motor nerve paralysis the tetanic symptoms of spinal stimulation appear" (p. 138).

This is a specimen of the latest scientific (?) teaching on this subject, as developed by recent physiological experimentation. It is certainly not encouraging. If the process goes on it will soon be a matter of extreme difficulty to prescribe drugs at all. For who would care to employ belladonna as an excitant to the spinal cord, believing that at the same time he was paralyzing its motor nerves?

If the reader will refer to the experiment with atropia, he will find that there is no proof to be found there of spinal stimulation. The presence of this latter state is a mere inference drawn from premises which are unproven, as the following will show. Here is the process of induction:

Atropia produces tetanus; *tetanus is due to spinal stimulation.* Therefore atropia is a spinal stimulant.

The allegation placed in italics is unproven. As a consequence, the conclusion is worthless as a logical inference, and is of no value, except as a makeshift at the explanation of phenomena where no other explanation is possible.

But the allegation placed in italics is not only unproven; it is untrue. There is proof that tetanus proceeds from spinal paralysis, direct and reflex. Dr. Ringer states that "certain poisons, like gelseminum and buxus sempervirens produce *at the same time* both weakness of natural co-ordinated reflex action (cord-paralysis) and tetanus. Thus in the case of these drugs, soon after poisoning, *the reflex function becomes much weakened, then distinct tetanus ensues.*" . . . . "In such a case it is impossible that the tetanus should depend on stimulation of the cord; for we have seen that *the tetanus was preceded by considerable depression of the cord, and continues till the depression ends in extinction of cord function.*" So also in some experiments on frogs, in which the spinal cord was cut and the brain destroyed, reflex action continuing for several days, Dr. Ringer observed that "soon after, but sometimes before co-ordinated reflex action began to decline, on striking the animal between the shoulders, the legs shot out in a tetanic manner, and *as the co-ordinated reflex action further declined, tetanus increased and became distinct.*" . . . "Here it is *impossible that tetanus could depend on stimulation of the cord, for it occurred in a dying cord*" (*Lancet:* Braith. Retros., July, 1877, p. 99).

The experiment of Prof. Stannius, mentioned above, in which ligature of the vessels leading to the limb produces tetanus, is an example of this state from simple reflex paralysis. Dr. W. B. Carpenter states that the complete arrest of blood in a limb produces paralysis of the sensory nerves ("Human Phys.," p. 353), the reflex effect of which on the spine and motor nerves is necessarily paralyzing also.

As tetanus has never been proved to be due to stimulation of the cord, there is no reason to assume that examples like the foregoing are isolated or exceptional, since, for anything that appears to the contrary, they may be illustrations of the general rule. Indeed, the most complete and prolonged contractures of muscle are invariably associated with the worst forms of paralysis, as pathological records fully prove.

The facts just detailed therefore justify the following syllogism:

Atropia produces tetanus; tetanus is due to spinal paralysis. Therefore atropia is a spinal paralyzer.

The objection taken to the former syllogism cannot apply here, because each of the premises is fully proven, and the conclusion follows in a proper logical manner. It will hence be apparent that the experiments relied on to prove that atropia is a spinal stimulant do not prove this, and that the conclusions based upon these experiments have been fallacious and unjustified. It is indeed surprising how such an idea could have been seriously entertained as that a drug, the embodiment of a natural force, after inducing the profound and prolonged paralysis recorded above, which in one experiment is admitted to have lasted several days, could then *reverse its mode of action* of its own accord, as it were, and thenceforward assume the *rôle* of a stimulant for *many days thereafter, during which life is slowly dying out.* Such an explanation of the phenomena is surely one which itself requires explanation more than the simple facts themselves; and were its merits other than they have been shown to be, it would still be of value only so long as no other equally rational explanation is offered.

But this experiment with atropia admits of another explanation, which accords with the facts and is justifiable and consistent with itself and with other physiological data. It is, that with the minimum *fatal dose,* the spinal cord and motor nerves die slowly. The ever-progressing paralysis at length renders nervous life wholly extinct, and then the muscles are free to exert their "great property of contractility, as they do, by passing from spasm into

tetanus. With a large dose, the life of the motor nervous system succumbs more promptly; and hence the muscles are sooner set free to contract, thus blending the earlier and later effects of the drug together—paralysis with tetanus—a condition which, interpreted in the fallacious light of the theory of the day, gave rise to the assumption that these states represent opposite conditions of the motor centres, whereas, in reality, they are parts of the same process; the paralysis indicating the withdrawal of the nerve from the influence of the central ganglia, and the tetanus the cessation of nervous control over the muscle. The facts of pathology abundantly illustrate this doctrine.

The experiments of the Edinburgh Committee, as reported by Dr. J. Hughes Bennett, show, both in rabbits and dogs, a uniform progression from *weakness and immobility to "paralysis, tremors, spasms, convulsions," and tetanus*, as the result of atropia poisoning. What folly to attribute the symptoms of the latter stages of this fatal descent to a process of stimulation, at the very time when death is about to close the scene!

The apologist for this doctrine may here demur, and claim that the tetanic spasms are not attributed to a *healthy* increase of normal nerve-activity, but are due to "a *morbid* exaltation of the functions of the cord, as a nerve-centre." (Dr. Hammond.) This "morbid exaltation" also passes under the name of "augmented irritability," and is evidently something separate and distinct from normal nerve-action. Is there any proof that nerve-cells generate two kinds of nerve-force, one normal, the other morbid? Until this is proved, how is the presence of this intruding force to be accounted for? It must have some origin, and as normal nerve-force is admittedly enfeebled, or in abeyance, the "morbid" variety must have its source extraneous to nerve-function. This is all the more evident, since it feeds upon exhaustion and grows stronger as life grows weaker. Paracelsus and Van Helmont had their "imaginary demon," the Archœus, residing in the tissues and organs, to perform offices of this kind; and it would really appear that modern medicine has not yet been able to dispense with him. If there is any other or better explanation of the origin of this extraneous "morbid" force, than that of Paracelsus, it is for those who invoke it to explain its presence.

How true it is that nerve-force proper is really here enfeebled, is shown by Dr. W. B. Carpenter, who, while in accordance with the theory of the day, regards tetanus as consisting in "an undue excitability of the whole series of spinal ganglia," nevertheless attributes the idiopathic form of the disease to "malnutrition of the cord, consequent upon impoverishment or deprivation of the blood," just as Dr. Hammond attributes it to "cold and damp," "poor diet," "ill-ventilation," etc., all of them being conditions highly unfavorable to nervous vigor. The cure of a larger percentage of cases of tetanus by "stimulants," than by any other class of drugs is a striking fact in this connection (Dr. Hammond), and is also a singular commentary on the alleged excitement of the spinal nervous system in this disease.

In the production of tetanus by atropia there has been no pretence that the stimulation the spinal cord was said to be undergoing was of the "morbid" kind. No Archœus was invoked here. The cord was excited to generate increased nerve-force of the normal type; but as Dr. Ringer states in the opening quotation, the simultaneous paralysis of the motor nerves prevented this increased nervous activity from displaying itself! And what is still more wonderful, it is said that the spinal cord and its motor nerve-trunks could only be brought into accord by excluding the atropia-poisoned blood from the periphery of these nerves. The statement that tetanus does not result from atropia, unless the motor nerves are protected from its influence by ligaturing the vessels, appears to be in contradiction to the facts of other experiments, as it is of the one quoted in a previous page, and also of the experiments of the Edinburgh Committee, in all of which tetanus speedily resulted without any ligature of the blood-vessels. After what has been already advanced, these contradictions and anomalies are simply left with the reader, as a curious specimen of modern medical literature.

Dr. J. Milner Fothergill is enthusiastic in regard to the good qualities of atropia, as a "direct stimulant to the respiratory centres." He offers no special proof of this statement, beyond conclusions drawn from its clinical use; and such conclusions, by themselves, are eminently unsatisfactory and open to contradiction. Thus, while Dr. Fothergill holds that atropia antidotes opium, directly through its stimulating effect on the respiratory centres in the medulla ("Antag. of Ther. Ag.," pp. 98, 99, 114), Dr. J. H. Bennett, in his report of the Edinburgh Committee, finds, that any beneficial action of atropia here is only "within a limited area," and then that its mode of action is "by *contracting the blood-vessels*, and thus diminishing the tendency to cerebral and spinal congestion," produced by the opium or morphia (pp. 46, 97). Here the effects of the atropia are accounted for, by a high authority, without any reference to the alleged stimulation of the respiratory centres.

Dr. Fothergill further tells us of belladonna, that "there is a whole mass of evidence from various sources, that it has a powerful action on the respiratory centres" (*Ib.*, p. 112). But all he adduces is a statement from Meigs and Pepper that this drug is useful in whooping-cough; an observation from Dr. Kelly, that children require larger doses and are more tolerant of it than adults; and that Dr. Hyde Salter found it "useful in cases of asthma." This "mass of evidence" may be true, without implying any special action of the drug upon the respiratory centres. As a proof of the thesis he advanced it is eminently unsatisfactory.

Dr. Fothergill quotes Bezold and Bloebaum to prove that atropia does not produce its effects on the respiration through the vagi (p. 99). If not through the vagi (which are the chief agents—the very arms, so to speak—of the medulla oblongata) the presumption is, that the "acceleration of breathing" referred to is produced otherwise than through the respiratory centre: through the circulation for example, which belladonna modifies by reducing the calibre of the arterioles, with the characteristic effects of this result; a quickening of the blood stream, increased oxygenation of effete materials and temporarily improved nutrition, all of which this drug accomplishes in strict accord with its character as a paralyzer, as has before been pointed out.

The tendency has been of late to over-rate this *quasi* stimulation. The results of the Edinburgh Committee show that as an antidote to calabar bean its antagonism is "very limited," "even more limited than Dr. Fraser has indicated." As an antidote to morphia, besides finding its antagonism only "within

a limited area," they add, that "in man it would be too dangerous and uncertain a remedy to depend on in cases of poisoning by opium, or any of its salts" (pp. 55, 97). Dr. J. Harley, indeed, denies this antagonism altogether, and as the results of his experiments, holds that "belladonna cannot, in any sense, be regarded as an antidote to opium, but in large doses is the very reverse." The enthusiasm which incites Dr. Fothergill to regard atropia as "decidedly stimulating" in these cases, is consequently dangerously misleading.

Even the delirium and hallucinations which are among the characteristic effects of this drug, and which have been sometimes regarded as evidence of a stimulating action, are shown by Dr. Anstie to be "symptoms developed in the midst of a spreading paralysis of the nervous system, and rightly understood, they form an important part of the evidence of this paralyzing process" ("Stim. and Nar.," p. 182). It is to be hoped that in regard to few drugs have so many fallacies been promulgated as has been the case with balladonna and its alkaloid atropia.

In view of the foregoing facts and considerations, how much credence is properly due to the statements on the relations of the nervous system to muscular spasm and tetanus, in our *quasi* scientific publications? Is it not time that the basis on which opinions rest were looked to, and where this is found to be purely imaginary, or at best hypothetical, and at the same time at variance with reason and common sense, as well as with physiological science, ought it not to be discarded, and a basis sought for the explanation of the phenomena, at once natural, rational, and in full accord with sound physiology? Will not the MEDICAL RECORD lend its powerful influence in favor of this good work, and lead the van in a reform, which may be delayed, but is sure to come?

SYMPATHETIC NEURO-RETINITIS.

By DAVID WEBSTER, M.D.,

NEW YORK.

(Read before the Medical Society of the State of New York, at its seventy-fifth annual meeting, February 1, 1881.)

ALTHOUGH the great Von Graefe, the father of modern ophthalmology, recognized the existence of such an affection as sympathetic neuro-retinitis, and reported two cases of it that came under his observation, the literature of the subject is still somewhat scanty, very little reference to it is to be found in the standard text-books on the eye. Stellwag, whose work is justly celebrated for its comprehensiveness, makes only a single allusion to it. "In individual cases," he says, "sympathetic inflammation of the retina is said to have been caused in the second eye" (Fourth American Edition, page 297). Schweigger mentions it only to throw doubt upon it. "It is very difficult," he says, "in observing any particular case, to be convinced of its sympathetic character. For instance, the case of choroido-retinitis described by Von Graefe, which I know perfectly well, since I observed it with him, presented such a peculiar appearance that Von Graefe regarded its sympathetic nature as probable. But it requires a number of such cases to furnish satisfactory proof of the correctness of such an opinion" (Farley's Translation of the Third German Edition, page 351). More is to be found on the subject in the Third American Edition of Wells than in any other of the text-books. The editor discusses the subject briefly but judiciously, basing his remarks upon the paper by A. Alt, M.D., "On Sympathetic Neuro-retinitis," in the "Transactions of the International Ophthalmological Congress for 1876," and the paper by the same author "On the Anatomical Causes and the Nature of Sympathetic Ophthalmia," in the "Archives of Ophthalmology and Otology," vol. v., page 395 et seq.

Neither Carter nor Macnamara makes the slightest allusion to the subject. Carter, however, says: "I believe, indeed, that many more cases are sympathetic than those in which the course of events can be clearly and unmistakably traced" (American Edition, page 116), and in this opinion most of us, I think, are ready to concur.

Von Graefe published his cases in 1866. Dr. Thomas R. Pooley, of this city, was the next to call attention to the subject. In 1871 he reported "Two Cases of Sympathetic Ophthalmia distinguished by the Occurrence of Neuro-retinitis" ("Archives of Ophthalmology and Otology," vol. ii., page 284).

Alt, in the paper referred to above, gave a resumé of Von Graefe's and Pooley's cases, and added to the number three that had come under his own observation, making seven in all. To these seven I beg leave to add the following two cases, one of which occurred in the private practice of Dr. C. R. Agnew, the other in his clinic at the Manhattan Eye and Ear Hospital.

CASE I.—F. G——, a boy eight years of age, came under observation August 29, 1879. His father said that fifteen months before, while stooping down in the garden, he struck his right eye against a stub, and "burst" it. The lacerated globe healed with a high degree of atrophy, a few lines of semitransparent cornea remaining. The shrunken eye is soft, and the child shrinks from pressure upon it through the lids, and says it hurts him.

Less than three weeks ago his parents first observed that he did not see well with his *left* eye. The vision of this eye is now reduced to $\frac{1}{200}$. The eye is somewhat sensitive to light, but painless, not tender on pressure, and its external appearances are normal.

For the better examination of the interior of the eye the pupil was widely dilated by atropine.

Ophthalmoscopic examination revealed floating opacities in the vitreous humor, great swelling of the optic disk and adjacent retina, and plaques of retinal exudation and retinal hemorrhages scattered over nearly the whole of the fundus. The retinal blood-vessels were extremely tortuous, and were in many places obscured by the exudations and blood extravasations. The optic disk could only be located by the convergence of the retinal vessels, and by its greater elevation.

The atrophied eyeball was enucleated on the same day and placed in Müller's fluid. It was found to be adherent to the surrounding tissues all the way back to the optic nerve entrance.

The patient was at once placed upon mercurial inunction, which was continued until his mouth was slightly touched. The ointment was then washed off, and a saturated solution of iodide of potassium given internally, commencing with five minims thrice daily, and increasing the dose two minims a day.

September 23d.—The dose of the iodide has been increased to seventeen minims. The patient comes to the office for the first time since the enucleation. His vision has risen to $\frac{20}{200}$. The intraocular appearances are much improved.

September 30th.—The dose of the iodide has been increased to thirty-one minims. The patient has diarrhœa. The vision has continued to improve, and

is now $\frac{15}{100}$. To reduce the dose of iodide to fifteen minims of the solution.

October 9th.—Vision $\frac{20}{100}$. There is no sensitiveness to light, and the vitreous opacities have mostly cleared up. The ecchymoses and exudation plaques have mostly disappeared from the retina, and the outline of the optic disk begins to appear.

November 8th.—Vision remains $\frac{20}{100}$. The vitreous is perfectly transparent. The optic disk is white and atrophic-looking, and there is a crescent of choroidal atrophy at its temporal edge. The retinal vessels, both veins and arteries, remain quite tortuous, and are decidedly smaller than normal. There are no remains of the hemorrhages and exudations.

The patient was directed to take one one-hundredth of a grain of sulphate of strychnia twice a day. This was continued for several months, when all treatment was abandoned.

April 5, 1880.—Vision $\frac{20}{70}$. The appearances of the fundus have not changed since the last examination.

The enucleated eyeball was examined by Dr. T. Mitchell Prudden, who has kindly given me the following report:

"June 7, 1880.—The examination of the eye of F. G. revealed most extensive changes of nearly all parts of the organ except the sclera.

The cornea was drawn to one side, and thickened at that side, and was permeated with small blood-vessels, especially in the periphery.

The atrophied iris and ciliary body, a mass of new-formed connective tissue growing from the region of the sclero-corneal junction of one side, together with the remnant of the lens capsule, were intimately joined together, forming a dense, shapeless mass in the anterior segment of the eye, nearly obliterating the anterior chamber. This condition of affairs was evidently the result of an extensive plastic cyclitis with subsequent atrophy and retraction.

The lens body had almost entirely disappeared, a small fragment only being left over the remnant of the displaced ciliary body at one side.

The retina was separated from the choroid in the entire circumference (in a meridional section) and, for about two-thirds of its extent, was shrunken together into a consolidated mass near the centre of the globe. For the rest of its extent it lay nearly parallel with the choroid, but separated from it by a narrow space. It presented throughout the lesions of diffuse, interstitial retinitis with atrophy, a few small cysts being found.

The vitreous was replaced by a finely granular, structureless substance (probably fluid), containing a few scattered cells.

The choroid was separated from the sclera over a considerable area, but its minute structure was not much changed.

The larger cavity on one side, between the retina and choroid, and the smaller one on the other, between the choroid and sclera, were filled with a structureless (probably fluid) substance, containing here and there single or groups of pigmented retinal epithelial cells."

Case II.—William H., twelve years of age, got some unslacked lime into his left eye in the early part of August, 1880. When he presented himself at the Manhattan Eye and Ear Hospital, about two weeks after the burn, the eyeball and eyelids were inflamed, and the formation of symblepharon had already proceeded so far that all attempts to prevent it proved abortive. The eye healed with total adhesion of the lids to the globe. The lids were also attached to one another, for a line or two at both ends of the palpebral fissure. The very narrow strip of cornea which could be exposed being opaque, there was, of course, only perception of light. The cicatricial contraction incidental to the healing process had also produced inversion of the eyelashes.

It was feared that this unfavorable condition of the left eye might give rise to sympathetic inflammation, and the friends of the patient were instructed to watch the right eye, and if any unusual symptoms presented themselves to bring him to us without delay.

On November 30th his mother brought him to Dr. Agnew's clinic at the College of Physicians and Surgeons, and stated that only the day before she had noticed, for the first time, some redness of the fellow eye.

We found the condition of the injured eye unchanged. The ciliary region of the right eye was deeply injected, and sensitive to pressure, the pupil was small and sluggish, and the eye was watery and sensitive to light.

We dropped in some of an eight-grain solution of sulphate of atropia, ordered a four-grain solution of the same to be dropped into the eye several times that night and the next morning, and instructed the mother to bring him to the hospital the following afternoon for enucleation.

The boy was brought to the hospital the next day (December 1st), as directed. The ciliary redness, lachrymation, and photophobia still persisted; the pupil was dilated to about one-half its maximum size, but was perfectly circular. Vision was $\frac{20}{30}$ without a glass, and was raised to $\frac{20}{15}$ with a + $\frac{1}{20}$. The sensitiveness of the eye to light and the lachrymation interfered considerably with the visual and ophthalmoscopic tests, but it was noted that the supero-nasal border of the disk was blurred, that the nerve and retina were hyperæmic, and that some of the retinal veins were tortuous.

It was decided to enucleate the injured eye, not so much on account of the commencing neuro-retinitis of the right eye as on account of the high degree of hyperæmia of the ciliary body and iris, which it was believed would, if not promptly checked, lead to irido-cyclitis, and the eventual loss of the eye.

Accordingly, the child was at once placed under ether, and the eye was, with some difficulty, excised. No speculum could be inserted until the external canthus was freely slit, and the eyelids cut away from the anterior surface of the eyeball. The globe was everywhere attached to the surrounding orbital tissues by a tough material which was divided, with the use of considerable force, by means of the strong curved scissors commonly used for cutting the optic nerve.

The day following the operation, the ciliary redness and lachrymation of the fellow-eye had mostly passed away, and the pupil had become dilated nearly to its normal extent. His urine was carefully examined, chemically and microscopically, and found normal.

On December 8th, one week after the operation, the right eye was normal in its external appearances, the redness, photophobia, and lachrymation having entirely passed away, and the pupil being widely dilated by the atropine which had been assiduously used from the first.

The ophthalmoscope showed well-marked symptoms of neuro-retinitis. There was swelling of the optic disk (H. $\frac{1}{6}$), with obscuration of its whole outline, increased fulness and tortuosity of the retinal veins, and radiating from the *fovea centralis*

were fine, hair-like opacities, lying closely side by side, and occupying a region about twice the size of the optic disk. Vision $\frac{20}{70} : \frac{20}{20}$ with $+ \frac{1}{18}$ s. $\supset + \frac{1}{42}$ c. ax. 10°.

December 13th.—Examined by Drs. Agnew, Pomeroy, Risley, and others. Disk H. $\frac{1}{2}$ and distant parts of fundus H. $\frac{1}{4}$,—showing an increase in the swelling of the disk and retina.

December 14th.—The patient was placed upon mercurial inunction.

December 21st.—The mouth being slightly touched the inunction was stopped. The local use of atropine was also stopped.

December 31st.—The patient comes with his ciliary region again slightly reddened, and with some lachrymation and photophobia. Dropped in a four-grain solution of atropine, and after an hour the pupil was dilated about two-thirds, and circular. He was directed to resume the use of atropine three times daily. Disk H. $\frac{1}{4}$ and the neuro-retinitis evidently subsiding.

January 3, 1881.—Pupil widely dilated. All external symptoms of irritation have passed away. To use the atropine once a day.

January 14th.—The neuritis has nearly disappeared, the diskal edge being indistinctly visible throughout its whole extent. The retinal striations radiating from the macula lutea remain about the same. Vision $\frac{20}{70} : \frac{20}{20}$ with $+ \frac{1}{18}$ s. $\supset + \frac{1}{42}$ c. ax. 180°. Visual field and color-perception carefully tested by Dr. J. B. Emerson, and found normal. The cavity of the enucleated eye has so healed that the eyelashes are everted, and thus do not irritate the conjunctiva.

The following is Dr. Prudden's report of the microscopic examination of the enucleated globe :

"In the eye of W. H., the general relation of the parts was so much disturbed artificially that I must content myself with a somewhat brief description of them.

The sclera in the anterior half of the ball was covered on the outside by an unusual amount of loose connective tissue, containing, especially near the sclero-corneal junction, a considerable number of dilated blood-vessels. The sclera itself was normal in structure.

The cornea was excessively atrophied, and converted into a richly cellular, irregular mass of connective tissue, over the middle of which, in front, a small lenticular mass of very vascular granulation-tissue lay. Over the surface of the atrophied cornea, as well as at the sclero-corneal junction, a very considerable proliferation of the epithelium had occurred, with hypertrophy of the papillæ in the latter region.

The atrophied cornea was bound behind firmly to the iris by well-formed new connective tissue, and the iris, lens, and ciliary body were drawn strongly to one side by a cyclitic membrane which was much more considerably developed on one side than on the other, so that the lens lay behind the ciliary body on the side of the most considerably developed cyclitic membrane. These parts, iris, ciliary body, and cyclitic membrane, formed a solid mass of tissue enclosing the lens, which was little changed except for the presence just beneath the capsule of numerous very small ovoidal cavities. The iris itself was unusually dense in structure, and thickly infiltrated with small round cells.

The vessels of the choroid were distended with blood throughout, and its tissue infiltrated with thickly-scattered, small, dense collections of pus-cells.

The *pars ciliaris retinæ* was involved in the anterior changes, while in the posterior half of the globe the retina seemed normal, except that the rods and cones, especially the latter, were considerably swollen, and the ganglion cells of the inner layer partially disintegrated. The eye was preserved, however, in too small a quantity of Müller's fluid, which, I presume, had not been frequently changed. So that I doubt if any considerable significance should be attributed to such changes in the delicate nerve-elements—although the swelling of the cones *was very marked.*

The anatomical diagnosis would accordingly be : symblepharon, conjunctivitis, keratitis atrophica, irido-cyclitis, choroiditis purulenta (and possibly commencing atrophia retinæ)."

In the seven cases reported by Alt both eyes were lost in only two instances. In one case the visual result was not given, but is inferred to have been good, as the "degree of diminution of sight is stated to have been slight," and after enucleation of the blind eye the other "gradually improved." In the four remaining cases the final vision was $\frac{5}{200}$, $\frac{1.6}{200}$, $\frac{20}{30}$, and $\frac{20}{20}$, respectively. In my first case the final vision was $\frac{5}{200}$, and in the second case $\frac{20}{20}$.

It may be worthy of remark that in five of Alt's cases and in one of mine—that is, in six out of the nine cases—detachment of the retina was one of the lesions in the eye producing the sympathetic inflammation.

My second case here reported is the only one I remember to have seen in which sympathetic ophthalmia was caused by symblepharon.

Dr. Mathewson, of Brooklyn, informs me that a case has fallen under his observation in which both eyes were lost by sympathetic inflammation caused by symblepharon in one of them.

EYE SYMPTOMS IN LOCOMOTOR ATAXY.

By A. D. ROCKWELL, M.D.,

ELECTRO-THERAPEUTIST TO THE NEW YORK STATE WOMAN'S HOSPITAL.

In an extract * from a paper by Dr. J. Hughlings Jackson on the above topic, he refers to the very frequent association of atrophy of the optic nerve with locomotor ataxy, as well as to the fact that as far back as 1868 Charcot had pointed out that the great majority of women admitted into La Salpêtrière for amaurosis have, sooner or later, manifestations of tabes.

This has recalled to mind two cases that have lately come under my observation, and which are the more interesting from the fact that the patients were brothers.

Mr. H. W——, aged forty-five years, came to me in April, 1879, with well-marked symptoms of spinal sclerosis.

The sight was much affected, and further examination, in connection with Dr. W. A. Hammond, revealed evidences of atrophy of the optic disk. It was found necessary, of course, to give an unfavorable prognosis, and the patient passed from under my care. He died about a year subsequently, and it is but justice to say that this speedy termination of the case was predicted to me by Dr. Hammond. It may, however, be said that death was undoubtedly hastened by the industrious aid of a charlatan and so-called electrician at Saratoga, who informed him that "his spine was healthy, but that his liver was

* New York MEDICAL RECORD, February 12, 1881.

diseased," and who submitted him to daily séances of an hour each.

Mr. J. W——, aged forty years, brother of the above, consulted me in January, 1880. He suffered from persistent insomnia, and stated that for several months his eyesight had been gradually failing. The patient was quite healthy in appearance and vigorous physically, and presented no symptoms characteristic of ataxy. An ophthalmoscopic examination by Dr. H. Knapp, with whom a consultation was requested, readily revealed the existence of white atrophy of the optic nerve. The patient soon after left for his home in a distant city, and from information lately received I learn that his general health continues fair, but that there has been a steady increase in the gravity of the local trouble, so that the sight is now very indistinct.

Although as yet no symptoms have appeared indicating that the cord is involved, it is to be feared that sooner or later ataxic symptoms will follow. Dr. Jackson states that in one case optic atrophy preceded the spinal complication by ten, and in another by twenty years. In looking over the notes of the first of my two cases above given, I find it recorded that the patient first observed some impairment of vision associated with slight darting pains in the legs before there were any observable symptoms of inco-ordination of movement. This accords with Dr. Jackson's observation that "many men who had white atrophy of the optic disks had also lightning pains in the limbs; and later, on making a distinction as to the kind of atrophy, he concluded that the pains were a symptomatic link between *uncomplicated* amaurosis and locomotor ataxy."

A CASE OF
CICATRICIAL CONTRACTION OF THE THUMB AND FINGERS, AND OF THE PALM OF THE HAND, RESULTING FROM A BURN.

By ALFRED C. POST, M.D., LL.D.,
NEW YORK.

(Presented to the Medical Society of the State of New York, February 2, 1881.)

Emily Louisa Barnum, eight years of age, presented herself at my clinic in the medical department of the University of the City of New York, December 11, 1880, with the following history: At the age of two years she fell with the palm of her left hand resting on a hot stove, by which the integument of the hand was severely burned. After the separation of the sloughs the sore was slow in healing, and no efficient means were employed to guard against deformity. The consequence was that the thumb and fingers were drawn toward the palm of the hand, and their motions were very much restrained. When she came under my observation the hand was bent somewhat backward at the wrist. The palmar surface was occupied by dense cicatricial bands passing off to the thumb and fingers, and fixing the fingers in a bent position, at the metacarpo-phalangeal articulations, at an angle of about 110°. They could not be extended beyond this angle, but the flexion could be increased. The cicatricial band passing to the middle finger was more dense than the others. The next in density was that passing to the little finger. The index and middle fingers were joined together by a dense cicatricial web, extending from the normal situation of the commissure, half way to the articulations of the first and second phalanges with each other. On December 11th I had the patient etherized, and operated by making transverse incisions through the cicatricial bands, throughout their whole breadth and thickness. Four parallel incisions were made through the band which passed to the middle finger, three to that which passed to the little finger, and two through each of the bands passing to the thumb and to the index and ring fingers. After these incisions had been made, the hand could be unfolded, and the thumb and fingers fully extended. The wounds were then washed with a solution of carbolic acid, 1 to 40, and a felt splint stiffened with shellac was moulded to the dorsal surface of the forearm, hand, and fingers, separate divisions of the splint being adapted to the thumb and to each of the fingers. The different parts of the limb were secured to the splint by strips of adhesive plaster and a roller-bandage. The patient was then sent to the Presbyterian Hospital for further treatment. At the next dressing narrow strips of hoop-iron were attached to the digital portions of the splint, extending along their dorsal surfaces, and continuing up the dorsal surface of the hand and forearm, more than half way from the wrist to the elbow, being firmly secured to the felt splint by strips of adhesive plaster. The object of these bands of iron was to resist the tendency of the flexor muscles to bend the felt splint, and with it the fingers. The dressings were repeated at intervals of two days, the wounds being washed at each dressing with carbolic acid, 1 to 40. Passive motion was also freely resorted to, the whole hand, and each joint of the thumb and of each finger being alternately flexed and extended. These movements, especially those of flexion, were quite painful to the patient. But the pain was transient, ceasing almost immediately when the movements were discontinued. As the wounds granulated, nitrate of silver was applied, as soon as the granulations became exuberant. Care was also taken to restrain the growth of granulations by compressing them with strips of adhesive plaster.

On January 17, 1881, the wounds having all healed, I made a free division of the cicatricial web uniting the index and middle fingers, extending the incision both on the dorsal and palmar surfaces, a little further up the hand than the commissures of the other fingers. After the oozing of blood had ceased I applied narrow strips of adhesive plaster around each of the separated fingers, crowding them closely up to the newly formed commissure. This process was repeated at each dressing, and a free application of nitrate of silver was made to keep down the growth of granulations which might have reproduced the web. The consequence has been that the two fingers have almost completely cicatrized, and the space between them has not been encroached upon. On January 21st the portion of the splint supporting the thumb was cut away, so that the thumb was left at liberty, and the patient was directed to give it as much exercise as she conveniently could.

On January 28th the portion of the splint supporting the little finger was in like manner removed, and similar directions were given with regard to the exercise of this member. In a few days I propose to remove the splint altogether. The cure of the case is virtually complete. The fingers are fully extended, and there is no trace remaining of the cicatricial bands by which they were drawn into a flexed position.

Note.—On February 4th, two days after presenting the case to the State Medical Society, I removed the splint, and directed the patient to exercise all the fingers as freely as she could.

Reports of Hospitals.

PRESBYTERIAN HOSPITAL, N. Y.

Service of Dr. ANDREW H. SMITH.

(Reported by John A. Wells, M.D., House Physician.)

CASES ILLUSTRATING THE USE OF ENEMATA OF DEFIBRINATED BLOOD IN PHTHISIS.

Case I.—Archibald Sinclair, aged twenty years, admitted August 18, 1880. The patient, at the time of his admission, was in the third stage of catarrhal phthisis. There was a cavity at the apex of the left lung. He was exceedingly anæmic, and had been rapidly emaciating. There was very pronounced hectic, with frequent and exhausting night-sweats. He had been losing steadily in weight before commencing the blood-treatment, notwithstanding the usual treatment of cod-liver oil and iron, combined with a most nutritious diet. His weight before commencing the blood-injections was 101 pounds.

November 25th.—Four ounces of defibrinated bullock's blood, to which four grains of chloral hydrate had been added, were administered per rectum at bedtime, in addition to the usual treatment.

December 9th.—The injections of blood have been administered every night since the previous note. After several injections had been given it was found necessary to reduce the amount to two ounces, the rectum not tolerating the original amount. By continuing the smaller amount for a few days, and then adding five drops of tincture of opium to each four ounces of blood, no difficulty was subsequently experienced in retaining the full amount. The weight of the patient, after two weeks' treatment, shows a gain of seven pounds. His entire appearance is changed. He has an excellent appetite, has had but one slight night-sweat, and is decidedly less anæmic. He expresses himself as delighted with his evident improvement. A steady improvement in weight and in his general condition has continued up to the time of this report, one month from the last date.

Case II.—Maria Durnin, aged twenty-two years, admitted November 13, 1880. The patient gave a very direct phthisical history for eight months past. There was very marked hectic, the evening exacerbations varying between 103° and 104° F. The cough was paroxysmal and violent. She was emaciated, without appetite, and for two months had been subject to constant vomiting. Her weight before commencing treatment was 101¼ pounds. A physical examination revealed a large cavity at the apex of the right lung, with a smaller cavity at the left apex.

November 27th.—Four ounces of defibrinated blood were administered per rectum at bedtime. Seven grains of oxalate of cerium were administered night and morning. The diet was limited to milk and beef-tea. No other treatment was employed.

December 11th.—The injections have been retained without difficulty. The weight of the patient has remained unchanged, but the improvement in her condition is beyond question. Food by the mouth is retained without difficulty for the first time in two months. There is an improvement in the appetite, the heavy coating has disappeared from the tongue, the cough is less frequent and less severe. There is a considerable color in the lips and cheeks, which were completely bloodless before commencing treatment. The patient is able to sit up the greater part of each day. Several weeks later the improvement continued.

Case III.—Edward Haggerty, aged forty-eight years, admitted November 19, 1880. Tubercular phthisis; third stage. There was a cavity at the apex of the right lung, with advanced consolidation at the left apex. An examination of the heart revealed aortic stenosis with mitral insufficiency. The urine contained one-third of albumen per volume, and large and small hyaline and granular casts. The patient was strikingly anæmic. Emaciation had been progressive and rapid. For several weeks he had been suffering from a profuse diarrhœa, with much gastric irritability. His condition was such that it was impossible to obtain his weight. For five days after his admission to the hospital he was unable to retain the simplest food. All the ordinary means for checking vomiting were employed ineffectually. The pulse was feeble and rapid, and there was such evidence of a rapidly approaching termination that an immediate unfavorable prognosis was given to the patient's friends. At this junction the defibrinated blood was exhibited in the following manner: four ounces of the blood, containing four grains of chloral hydrate, were injected per rectum every five hours. The precaution was taken to wash the rectum out with warm water once during each twenty-four hours. Three drops of laudanum were subsequently added to each injection, as the irritability of the rectum increased. Milk and lime-water in very small quantities was the only food allowed. The injections were employed every five hours for four days, during which time the patient was entirely free from vomiting. At the end of that time the stomach tolerated food, and the enemata were administered but twice in the twenty-four hours. Owing to the existence of internal hemorrhoids the rectum became very sore and irritable, after pursuing the treatment for two weeks, necessitating the discontinuance of the injections. The change in the patient's condition was very striking. He was able to sit up for several hours daily, his appetite was excellent, and he had no further difficulty with his stomach during the remainder of his stay in the hospital. There was an evident gain in weight, the cough was less troublesome, and a steady improvement in his appearance continued for the month following, when he was able to leave the hospital.

Death from Aneurism of the Aorta Pressing upon the Descending Vena Cava.—Dr. W. H. Taylor relates a case of thoracic aneurism which caused death in a somewhat curious manner. The patient, a man aged thirty-eight years, developed symptoms of aneurism quite suddenly, attacks of laryngismus being the most marked feature. A few days before death the face and neck suddenly became very œdematous; the neck especially was so swollen that it was as large in circumference as the face. The diagnosis of thoracic aneurism had been made. Upon autopsy a medium-sized aneurism was found upon the ascending arch. Its position was such that it undoubtedly pressed upon the superior vena cava.

A Case of Enteric Fever, without Lesion of Peyer's Patches, was reported by Dr. J. W. Moore at a late session of the Dublin Pathological Society. The patient died on the forty-sixth day, from croupous pneumonia. She had had all the typical symptoms of typhoid, including the roseola.

Progress of Medical Science.

Gastrostomy—Death on the Nineteenth Day after the Operation.—This operation by Prof. Sclifasowsky is another to be added to the list for cancerous disease of the œsophagus. At the time of the operation the patient's general condition was tolerably good, and during its performance nothing occurred to imperil the chances of his recovery. Immediately after its completion, sufficient food was injected into the stomach, and his daily nourishment afterward consisted of from ten to forty ounces of liquid food—beef-tea, milk, koumyss, wine, juice of meat, eggs, etc. Although the food was well digested and absorbed, the patient's condition grew rapidly worse, and he died from asthenia on the nineteenth day after the operation. Prof. S. advises the use of a double suture, a deep one made of catgut and a superficial one of silk, to secure a better adhesion of the stomach to the abdominal wall.—*Vratch*, No. 21.

Statistics Relating to Valvular Diseases of the Heart.—Dr. Nojnikoff, having examined the clinical records of 148 cases of cardiac diseases treated at the clinic of the Charkoff University, makes the following deductions: Valvular lesions formed 89 per cent. (132 cases); the remaining cases embraced other forms of cardiac disease. Valvular lesions of the left heart alone formed 93 per cent., of the right heart alone, 2 per cent.; both combined, 4 per cent. Insufficiency of valves formed 77 per cent.; stenosis, 22 per cent. They were distributed among the various valves in the following order—insufficiency of the mitral valve, 65 per cent.; of the aortic valves, 30 per cent.; of the tricuspid valve, 4 per cent.; stenosis of the left auriculo-ventricular ostium, 86 per cent.; stenosis of the aortic and pulmonary orifices, 6 per cent. each. Of these 132 cases of valvular lesions, 30 per cent. were associated with acute articular rheumatism. In 33 per cent. of the cases, the previous history of the patients mentions only the occurrence of malarial diseases; in 19 per cent. of the cases these two elements were found combined. In the remaining 16 per cent. he finds acute febrile diseases: endocarditis, from exposure, syphilis, alcoholism, sexual excesses, etc. Prof. Laskewitz was the first to point out the connection between the malarial poison and cardiac diseases. He frequently observed in patients suffering from acute malaria or malarial cachexia, painful palpitation, dyspnœa, and a peculiar irritability of the heart, indicating a pernicious action of the malarial poison on the organ, these effects yielding readily to quinine and arsenic. He considers the malarial intoxication as an important etiological factor in valvular diseases of the heart.—*Meditz. Vestnik*, 1880, Nos. 16–20.

Dermalgic Action of Quinine.—Dr. Zolatowitch states that every time he took quinine with a medicinal or experimental purpose it had a special effect on his skin. Once it occasioned an intolerable itching about the lips and anus, on two occasions it produced a severe balano-postitis, and again labial and anal herpes. A medical friend of his witnessed in one patient herpes of the prepuce, and in another the same condition of the prepuce and glans penis. —*Meditz. Obozrenie*, xiv., p. v., 90.

Treatment of Dysentery.—Dr. Enko used the following mode of treatment in 500 cases of dysentery: a dose of castor-oil is given, and if after copious evacuations the bloody mucus reappears, an enema composed of half a drachm of dilute muriatic acid to one pint of water, or of one grain of nitrate of silver to the same quantity of water, is given. The temperature of the enema should be between 60–65° F., and it is to be retained as long as possible. This is repeated in two hours. Dysentery usually ceases in two to four days, and it is very seldom required to repeat the treatment. In some severe cases, to prevent the recurrence of the symptoms, he orders pills containing nitrate of silver, $\frac{1}{10}$ grain; aqueous extr. rhubarb, $\frac{1}{3}$ grain; alcoholic extr. nux vomica, $\frac{1}{12}$ to $\frac{1}{4}$ grain; one pill three times a day. Coarse food should be avoided.—*Meditz. Obozrenie*, xiv., p. 291.

Faradization of the Large Intestine for Catarrhal and Ulcerative Colitis.—Dr. Karetzky has adopted the following plan of treatment in a case of chronic colitis, with ulcerations and atony of the intestines, which had resisted for five years every mode of treatment. The positive pole was introduced into the rectum, while the negative was moved along the entire length of the colon for a few minutes. After each application he also faradized with the brush the skin over the affected region. After the first few seances a very marked improvement was noticed in patient's general and local condition, and he recovered entirely after fifteen applications had been made.—*Vratch.*, 1880, No. 43.

A Case of Labor Obstructed by Complete Vaginal Atresia.—The patient was a young, healthy woman, twenty-three years old, of strong build, primipara. She menstruated for the last time July 20, 1879, but could not remember when she noticed the first fœtal movements. Labor-pains began on April 7th, and she remained in that condition until May 3d, when Dr. Berejsky was called in. He found her in a fair general condition, but the temperature was elevated, and the pulse 108. The pains were strong, and occurring every half-hour. External examination revealed transverse presentation. Fœtal movements were absent. Patient stated that they had ceased on the fourth day of labor. Neither fetal heart-sounds nor placental bruit could be heard. External genitals were found flabby, of normal size, and dry. The entrance into vagina was closed with an unyielding yellowish rose-colored membrane. On inquiry she stated that she noticed the closing of her vagina about the beginning of the second half of pregnancy, but the doctor could not obtain from her any explanation of its cause. There was no evidence of syphilis. An operation being consented to, he cut through the septum, which was composed of a dense, almost cartilaginous, cicatricial tissue, extending from the vulvar opening to the cervix. Toward the end of the operation a severe hemorrhage occurred. Child being dead, craniotomy was performed, and it was extracted. The woman recovered slowly, appropriate local treatment was adopted, and at the time of her discharge vagina permitted the introduction of the index finger.—*Vratch*, No. 10.

Changes in the Cutaneous Sensations and Urinary Secretion in the Course of Rheumatic Affections.—One of the most important recent contributions to the pathology of acute articular rheumatism has been that of Drozdoff, who has shown that during the presence of this disease there exists a marked alteration of the cutaneous sensation in the regions corresponding to the diseased joints. According to him, the sensation of pain is very much diminished, electro-cutaneous feeling is depressed to a marked

degree, and the appreciation of pressure may be almost entirely abolished, while the tactile and thermic perceptions remain normal or are even exaggerated. Dr. Vernjsky finds these statements correct in the main. In some cases he has noticed almost entire suspension of every form of sensation; but, on the other hand, he does not find any parallelism between the cutaneous and articular symptoms. Patients with severe joint-lesions may present very slight anæsthesia, and *vice versa*. He regards these two symptoms as coincident and depending upon a common cause. The cutaneous manifestations are also present in the chronic rheumatism of joints, and the intensity of both presents greater similarity. They are met with also in myalgia, but less regularly, and it is only when the lesion involves a very large group of muscles that they are distinctly marked.

He finds, also, that patients with rheumatic affections are apt to suffer from polyuria. In acute cases polyuria may be present throughout the entire sickness and for some time after recovery, or increased urinary secretion was observed only during an exacerbation. The same is true for chronic articular rheumatism. It occurs also in patients affected with myalgia of a severe type, and involving a large number of muscles. He publishes the histories of a number of patients illustrating the above statements. His conclusions are that polyuria and cutaneous anæsthesia are essential symptoms of rheumatism, and, together with the articular symptoms, are due to a lesion in the central nervous system. He points to the peculiar disposition of diabetics to suffer from rheumatism, and to the ease with which it can be produced in them by artificial means.—*Meditz. Obozrenie*, 1880, Nos. 23–33.

Action of Chloral Hydrate and Camphor Combined.—According to A. Doctman, equal parts of chloral hydrate and camphor produce a fluid resembling dilute glycerine, almost colorless, having the odor of both substances, and of a sweetish, burning taste. Half a drachm produces in man unconsciousness, deep sleep, acceleration of pulse and breathing. The pupils become dilated and do not react to light. Such were the symptoms in a case of poisoning he was called to treat. In five hours the patient awakened and entirely recovered. In animals, 0.25 to 1.5 c.c. of this fluid injected under the skin, produces, in five to ten minutes, a rapidity of pulse that cannot be counted, and an acceleration of breathing (160 per minute). The animal responds to the cutaneous irritation, but what is the most peculiar, a state of artificial catalepsy is produced; the animal will retain any position of limbs, trunk, or of the entire body we may give it. This condition of waxy flexibility lasts until the animal wakes up. In a larger quantity it produces fatal narcotism.—*Transactions of the Kazan Med. Society*, 1880, No. 22.

On the Action of Drugs on the Fœtus through the Medium of the Mother.—Dr. Kubassoff (Inaug. Diss.) states that even moderate doses of chloroform and chloral hydrate act on the fœtus, and apparently in the same manner as on the mother. The effect is produced in a few minutes after the beginning of the experiment. It consists at first in excitement, the fœtal movements are more active, the heart's sounds are louder, and the pulse is accelerated; then comes depression, manifested by the reversed state of the above symptoms. The action of opium and its alkaloids shows itself at a later period, and lasts longer than in the case of the first two drugs. It consists in marked irregularity and an intermittent state of the fetal cardiac action. He made a single experiment with digitalis, and the effect on the fœtus was very marked. He was always able to discover the presence of chloral in the fetal blood, its quantity corresponding to the relative weight of the mother and child. In some cases it reached 1.5 grains, being twice the normal dose for a child three months old. As the child gets one-twentieth of the amount given to the mother, he advises not to prescribe doses exceeding thirty grains.—*Meditz. Obozrenie*, xiv., p. 432.

Anæsthetic Action of Benzoate of Sodium on the Throat.—Dr. Fronstein recommends to spray the throat with a four per cent. solution of benzoate of sodium when the act of swallowing from any cause is painful, and in all cases where we desire to diminish the sensitiveness of the throat. He gives the history of two phthisical patients suffering from tubercular ulcers, who abandoned the use of solid food entirely, and in one of them even the swallowing of liquids (milk) caused great distress. In both cases an entire relief was obtained, but no improvement in the ulcerative process was noticed.—*Vratch. Vedamasti*, No. 447.

Local Use of Tincture of Iron in Erysipelas.—Dr. Hopadze has treated eighteen cases of erysipelas by painting the affected parts with the undiluted tincture of iron, which in all cases relieved the burning sensation. In a few cases it was necessary to repeat in ten to twelve hours. In four cases of spreading erysipelas this treatment localized the morbid process. After repeated painting the patient experiences a disagreeable puckering of the skin, which, however, readily yields to glycerine.—*Vratch. Vedamasti*, No. 447.

Physiological Action of Duboisin.—According to Epifanoff (Inaug. Diss., St. Petersburg), the physiological action of duboisin closely resembles that of atropine. After a temporary excitation of the cardiac inhibitory centres they are depressed, and the same effect is produced on the cardiac excito-motor centres. The vaso-motor centre is first irritated, afterward paralyzed. Although the breathing is accelerated, duboisin does not act on the respiratory centres. It dilates the pupil, paralyzes the muscular coats of the stomach, intestines, uterus, and bladder. Salivary secretion is depressed. Motor paralysis is produced by smaller doses of duboisin than of atropine.—*Meditz. Obozrenie*, xiv., p. 487.

Resection of the Intestines.—Dr. Cherni has reported to the Heidelberg Medical Society three resections of intestines performed within the last three years. In two cases it was made for the removal of the gangrenous parts due to strangulated hernia, and in the third for the removal of a cancerous growth. One of the first two cases died before the completion of the operation from the entrance of the intestinal contents into the lungs; the patient was almost in collapse at the time of the operation. The second case recovered entirely without any complications. Bowels moved on the eighth day. The third case recovered also, the operation resulting in a marked improvement of patient's general and local symptoms. She died six and a half months later, from the recurrence of her former illness. He insists upon the use of the spray and of Lister's dressing in this operation, and recommends the application of double sutures.—*Vratch. Vedamasti*, Nos. 446, 447.

A Case of Glossitis.—At the Clayton Hospital, Wakefield, the following case came under observation: W. H——, aged thirty years, entered the hospital with well-marked glossitis. The tongue was protruded two and a half inches beyond the teeth, and could not be retracted. The whole organ was very greatly enlarged and of a brawny hardness, due to exudation. A deep, ulcerated fissure existed where the tongue rested on the lower incisors. There was difficult, hurried respiration, the breath was fetid, and saliva constantly dribbled from the mouth. The dorsum of the protruded portion of the tongue was parched. The affection began twenty-eight days before. The patient said that he was nearly suffocated first, and that an abscess had burst at the root of the tongue a week from the commencement of the attack, and with only slight relief of the symptoms. On admission the temperature was 101° F. The mouth and all its contents were thoroughly cleansed with a strong solution of chlorate of potash in glycerine and warm water, and a piece of lint frequently wetted with water was kept over the protruded part of the tongue. The mouth was frequently syringed out. No perceptible improvement followed. Four days after admission a gutta percha support was made for the tongue, and fitted to the lower incisors. This afforded great relief to the patient, and the exudation began to disappear rapidly, so that forty-eight hours afterward he could retract the tongue within the teeth, after having been unable to do so for more than a month. The fissure simultaneously disappeared. Seventeen days after admission he was discharged cured. He had not had syphilis, nor did he show any signs of scrofula.—*The Lancet*, January 22, 1881.

Inception and Duration of Menstruation.—Dr. Bensenger found, from a series of five thousand six hundred and eleven women examined in Moscow and the surrounding provinces, that the first menstruation, on the average, began at the age of fourteen years, eight months and fifteen days. Among the upper classes it generally appeared earlier than among the lower classes. This, in the opinion of Dr. Bensenger, results partly from the more favorable hygienic condition of the former, and partly from their superior intellectual activity. Menstruation ended between the forty-third and forty-eighth years. The average number of years during which menstruation persisted was thirty-two. On the same subject Schlichtling concludes from a series of ten thousand five hundred and twenty-two cases in the Munich clinic, that the sixteenth year is the most common age for the first appearance of the menses in the city as well as in the country. The average duration of pregnancy is from 269.84 to 270 days. The minimum time in which a child can be developed and be viable is 236 days. The maximum duration of pregnancy is 334 days. Gestation terminating in summer continues on an average three days longer than gestation terminating in winter. Children born in summer are slightly longer and heavier than those born in winter.—*Med. Press and Circular*, February 2, 1881.

Catarrhal Pneumonia and Tubercle in the Human Lung.—In a series of papers which appeared in *The Practitioner*, Dr. D. J. Hamilton has extensively reviewed the subjects indicated by the title. The following is a synopsis of the main conclusions which he has arrived at:

1. Croupous pneumonia and catarrhal pneumonia are two totally different diseases, and ought not to have a common designation. Croupous pneumonia is merely an exudation of blood-constituents due to suddenly increased blood-pressure, while catarrhal pneumonia essentially consists in the over-stimulation and proliferation of the epithelial cells lining the alveolar walls.

2. Catarrhal pneumonia runs through three distinct stages: *a*, the acute or subacute; *b*, the caseous; and *c*, the excavating. The disease usually passes through all these in adults, but in children frequently proves fatal in the first or second.

3. In the acute stage the alveolar epithelium proliferates, and the cellular products derived from this process accumulate in the air-vesicles.

4. In the second stage these dry and become caseous, thereby losing their characteristic form.

5. In the excavating or third stage, the necrotic caseous material softens, and this softening is a purely chemical process, corresponding to the "ripening" of cheese.

6. When tubercle occurs in the lung, or in any other organ, it is always preceded by a caseous source of infection. This infecting source may be situated in the lung itself, or in some distant part. When situated in the lung itself, the tubercle is the secondary disease (secondary tubercle); but when in a distant part, the tubercle is the primary disease of the lung (primary tubercle).

7. The caseous virus in these two varieties is carried by a different set of vessels. In the secondary it is transported by means of the lymphatics, and the tubercles have merely a local distribution. In the primary it is conveyed by the blood-vessels, and in this case the tubercles are distributed generally, and usually throughout both lungs.

8. A tubercle, in all cases, when fully developed, consists of the following parts: one or more giant-cells, a surrounding reticulum formed by their processes, and a peripheral capsule.

9. The chief infecting sources of secondary tubercle of the lung are catarrhal pneumonia and interstitial pneumonia, accompanied by bronchiectasis. In both of these caseous matter is developed, and, being absorbed, excites the formation of tubercle in the surrounding connective tissues. The main causes of primary tubercle of the lung are softening cheesy glands and strumous abscesses.

10. Tubercle is liable chiefly to two degenerations. The commoner is the caseous. The other is the conversion of the whole of the tubercle elements into fibrous tissue, and is to be looked upon more in the light of the natural termination of tubercle development than as a degeneration. When it occurs extensively it produces a cirrhosis of the part.

11. Tubercle, under any circumstances is a connective-tissue growth, arising from the action of an acute irritant. The irritant is probably a ferment, generated in the softening of a caseous mass.

12. The hereditary tendency to phthisis is probably owing to an abnormally great susceptibility of the pulmonary epithelium to irritation. This seems to be borne out by the fact that, as persons advance in life, and when naturally epithelial cellular structures become more stable, the tendency to attacks of catarrhal pneumonia diminishes.

13. There is a form of catarrhal pneumonia in which the nodules are of small size, and are widely disseminated throughout the organ. It closely resembles tubercle in its naked-eye characters, but it is totally different from it in its actual structure and mode of development.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 5, 1881.

THE ENFORCEMENT OF THE MEDICAL LAW.

THE medical law in force in this State has attracted a great deal of attention, not only among medical men living within its jurisdiction, but among others of the profession in sister States. With the former it is generally conceded to be as perfect and consistent a law as can be enacted at present, while with the latter there is a general desire to accept it as a working model for their own wants.

On former occasions we have given the details of its provisions and commented upon their practical bearings. Unlike other similar legal instruments, it is simple in its design, liberal in its spirit, and consistent in its requirements. It is based upon a system of registration of all legally qualified practitioners. The responsibility of registering properly is thrown upon the individual who registers. Improper or fraudulent registration renders the individual guilty of the same liable to punishment for perjury. Medical men coming from other States to New York receive their licenses from the faculties of any of the incorporated medical colleges of the State. All persons who are not registered, or who are practising under cover of a diploma illegally obtained, are to be deemed guilty of a misdemeanor, and, on conviction, are to be punished by a fine of not less than fifty nor more than two hundred dollars. One-half the fine goes to the person or corporation making the complaint, and one-half to the county.

Such in brief are the provisions of the law. Their enforcement is as yet, however, a dead letter. The law has been in force for several months, and no conviction for violation of its provisions has yet been made. Not that there are too few persons throughout the State who are fit subjects for prosecution under the act, but that no means have been taken to bring them to justice. It is just upon this point that all the present interest in the law centres. The question why it is not properly enforced is one which is daily growing in importance. Not only is a large majority of physicians in this State waiting for some practical answer, but outsiders, residents of other districts, are manifesting the same concern.

It is quite evident that a start should be made in some way. The State Society at its recent meeting called the attention of the various county societies to the matter, and urged the adoption of some simple plans for testing the efficacy of the law. The State Society very properly did this in its official capacity, and it is to be hoped that some good will come of the recommendation. Each county is capable of taking care of offenders in its own district, and should do so with as little delay as possible. The official registration of each county is the natural basis for such proceedings. Some county societies have already published such lists, and have circulated the same among their members. But the movement is by no means as general as it should be. In some counties this list is still incomplete, that is to say, many legal practitioners are yet unregistered. But this is the fault of the delinquents only. It is not necessary to wait for them any longer. The action of the law is equal upon all. Such physicians as have stubbornly refused to comply with its provisions, should bear the penalty accordingly. It is misapplied indulgence to cater to their prejudices, and make the majority suffer for their shortcomings. If respectable physicians presume to transgress the law and place themselves on a par with the quacks, they have themselves to answer for the consequences.

Having obtained a complete list of registered physicians, it would be comparatively easy for each county society to enforce all the provisions of the law. It is well known that in several parts of the State there are many fraudulent registrations. For the majority of the latter conviction of perjury would be comparatively easy. All that is necessary is to make a beginning. It is asked from several quarters, with good reason, why the necessary movement is not made at this end of the line—why the lead is not taken by the Medical Society of the County of New York. It will certainly not lack for abundant material to work upon. Its first duty, however, will be to call to account such qualified practitioners as have not yet registered. The way will then be opened for the prosecution of the quacks.

QUACKERY AND THE RELIGIOUS PRESS.

WE find the following very interesting statement in a recent number of the *New York Observer*. Referring to the subject of charlatanry, it says: "Clairvoyants, mediums, *quacks*, and all the host that prey on the credulity of the public, would starve to death if their business depended on the patronage of the positively Christian portion of the community." Now this may

be largely true, and we trust that it is; even if not, no one can say that there is anything immoral in being gulled. But, that the assertion is not true as regards the religious journals, the columns of the *Observer* and all the rest of them show very plainly. Further than this, the religious editors are not the parties that are deceived, but they assist most flagrantly in imposing upon others. There is nothing innocent in their performances, for they do not buy the bottles, but are paid for their help in selling them. What are we to think when a religious journal announces that its patrons are the persons who least of all support quacks, yet publishes in another column the advertisement of a cancer-cure, of a specific for consumption, or some other preposterous cure-all? We find that nearly every religious journal publishes each week from two to three columns of quack advertisements. If the "truly Christian portion of the community" does not patronize charlatanry it is not because the Christian editor is not well bribed to induce it to do so. From corns to cancers there is no disease he will not announce in flaming head-lines to the public as a genuine specific.

> "What damned [mixture] but some sober brow
> Will bless it and approve it with a text."

Running down the last page of the *Observer* is an article on the prayer-meeting, and beside it another on blood-syrup—twin rivulets of spirituality and flaunting quackery. What truly Christian man can read the one without feeling a little tenderness for the other, especially if he has the stomach-ache (which the "syrup" invariably and permanently cures). Yet, says the *Observer*, quackery would totter if only truly Christian men supported it. And so perhaps it would if the religious press did not parade its claims with the exuberance and *abandon* of Barnum proclaiming his What is It?

It seems about time that at least the feelings of the medical profession on this point should be made plain to the clergy. Since first bringing up the subject we have been receiving numerous letters from every part of the country, and all expressing the same feeling of sympathy with our protests, and of indignation at the obstinate adherence of the religious press to its bargains with Mammon. We do not believe that there is one of the readers of the RECORD, nor one of the sixty thousand medical men in the country, who does not share the views we are expressing. Can the clergy and the religious press afford to ignore so widespread and deep a sentiment? And it is a sentiment which will easily end in a contempt for the Christianity that sees no harm in encouraging quackery and parading deceit.

That our Christian editors may know we are not expressing individual views, we quote here from a recent work by Dr. H. H. Kane, on the opium, morphine, and hashisch habits. Speaking of the causes leading to the extension of these habits, he says:

"Another matter in this connection needs attention, viz.: the lying pretensions of a few charlatans, notably in the West, who, by specious advertisements and deceitful lies, induce the victims to these habits to buy their medicines or come under their care or treatment. Their so-called specifics are simply preparations of opium or morphine, and their treatment is based upon the plan of substituting one form of the drug for another. . . . It is a shameful fact that the religious press tolerates the advertisements of these charlatans in their columns. *As a rule, the vilest advertisements are to be found in these newspapers.* Owing to the moral weight supposed to be carried by these sheets, owing to their large circulation among people who look upon every word contained as truth, these announcements and endorsements do the people an infinite amount of harm. Can it be that the financial 'backers' of these papers overrule the scruples of the religious editor? If so, while a good investment financially, it must be a very poor one morally."

We are very glad to see and acknowledge the fact that two journals, the *Evangelist* and the *Congregationalist*, have had no quack advertisements in their last few issues. We hope that it is more than a coincidence or than an indication of depression in the nostrum trade.

A MEETING TO CONSIDER THE PREVENTION OF INSANITY.

The National Association for the Protection of the Insane held a meeting in Boston recently which was notable in many ways. There was a large attendance, and the audience and speakers included the governor of the State and many prominent public and medical men.

The interest in the work of the association was shown by the very full reports and comments published in the daily press. The society has of late been receiving many new members, among whom are a dozen asylum superintendents, and two of these latter spoke at the meeting referred to. This and other facts tend to show that some impression is at last being made upon the closeness and conservatism of the Association of Insane Asylum Superintendents. The more liberal-minded in that body seem quite ready to appreciate the spirit and aims of the younger organization.

But, while making additions to its membership in all parts of the country, the remarks at the recent meeting indicated that considerable progress had been made in exciting public interest and securing practical reform. Governor Long, in a recent message to the Massachusetts Legislature, urged a number of new measures regarding the care of the insane upon that body. Some action in the matter, especially of classifying the insane, will undoubtedly be

taken. A bill has also been prepared providing for a staff of visiting physicians to the asylums. The work which has been done in Pennsylvania and the difficulties that have attended it, were pointed out very forcibly by Dr. Hiram Corson, Trustee of the Pennsylvania State Insane Hospital, in a letter read at the Boston meeting. He says, referring to the Association of Insane Asylum Superintendents: "Your counsel would be of infinite service in aiding our efforts to counteract the selfish, pernicious influence of this association. It may seem strange to you to hear me talk thus, but let me ask you what reform in management of the insane has originated in that society? What but the invention and use of closer confinement, more means of restraint and seclusion of patients, and determined resistance to the reforms urged by philanthropists, who have witnessed how greatly they have ameliorated the miseries and contributed to the successful treatment of the insane. I will not include all superintendents in this class of hostiles. There are many noble, humane, philanthropic men among them. . . . With much effort we have succeeded in preventing this association from having any participation in the erection of the Eastern State Hospital at Norristown, and in reorganizing the hospital at Harrisburg."

One of the topics of discussion, opened by a letter from Dr. Joseph F. Parrish, was that of the etiology and prevention of insanity. Dr. Parrish referred to the fact that insanity arose so largely among a wearied and restless class in whom bodily and mental vigor were sadly disproportionate. He believed that there ought to be more institutions for the treatment of persons who are only on the border-lines of insanity, in the "crazy circle" of Crichton-Brown. Dr. H. B. Wilbur, referring to the same subject, expressed his belief that insanity depended on predisposing causes —hereditary, social, and individual—rather than on exciting causes. While our civilization increased it, education and study did not, if applied in the proper way. Dr. Nathan Allen, speaking perhaps with the bias of a sanitarian, said that in his experience ill-health caused more insanity than any other agency. Dr. Allen and Dr. Kenniston, in a subsequent speech, asserted that intemperance was a great cause of insanity, and that any diminution in the former would equally affect the latter. Dr. W. W. Godding feared that we must accept brain disease as one of the penalties of a higher development, hinting a possible future arrest of a growth of mind aspiring to be god-like.

There were many other letters and speeches upon the above and kindred subjects. The discussions contained much that was suggestive, and the result of the meeting will undoubtedly be the giving of a fresh impulse to a cause which deserves so entirely the encouragement and support it is receiving.

NATIONAL APPROPRIATION FOR INVESTIGATING THE DISEASES OF ANIMALS.

The United States Senate recently passed a bill, sent up from the House, appropriating $10,000 for investigating the diseases of swine. Before passing it, however, an amendment was added appropriating $15,000 for investigating pleuro-pneumonia. It seems very probable, at the present writing, that the above sums of money will be expended by the Agricultural Department for the purposes indicated.

About a year ago we referred to investigations made by this department, and gave them some praise, as showing effort in the right direction. There has recently appeared, however, a report on "Contagious Diseases of Domesticated Animals" of a character so astonishing in some respects that it is but a duty to call the attention of our law-makers to it. The report contains the results of a few experiments, and it contains some statistics which are not without practical value. As regards original or scientific work, however, it is almost absolutely deficient. The pathological experiments and speculations are crude and ridiculous, and are generally but puny elaborations of the views of certain imaginative European experimentalists. More than half of the work is simply "padding," being composed of extracts from foreign or home journals, or reprints of long-forgotten monographs. The report also is gorgeous with many colored lithographs that have absolutely no value except to impress the minds of Congressmen.

We make these criticisms not because we would oppose any further appropriations, but because it seems a great misfortune that money, when granted for scientific purposes by our government, should not be used in the best manner possible. And if the Agricultural Department is supplied with money for further investigations, Congress ought to see that such investigations are carried on in a more efficient way than has just been done.

International Medical Congress at London, August 2 to 9, 1881.—The following programme has just been decided on for the Section of Medicine, of which Sir William Gull is President. List of subjects for discussion: 1. Localization of Disease in Brain and Spinal Cord so far as Pathognomonic and Diagnostic. 2. Trophic Changes of Nerve-Origin. 3. Vascular Changes, Functional and Organic, in Disease. 4. Primary Diseases of the Lymph System. 5. Gout, Rheumatoid Arthritis, and Rheumatism. 6. Forms of Renal Diseases. 7. Methods of Physical Diagnosis. 8. Therapeutic Methods: Revulsions, Bloodletting, Diet-Cure, Uses of Heat and Cold, Drug-Cure, etc.

A New Medical College in Japan.—An enterprising Englishman, named Dr. Palm, has established a hospital in Niigata, Japan, where he treats 5,000 cases annually. In connection with the hospital he also runs a medical college, and has English medical journals translated for the use of the students.

Reviews and Notices of Books.

A Practical Treatise on Diseases of the Skin. By Louis A. Duhring, M.D., Professor of Diseases of the Skin in the Hospital of University of Pennsylvania, etc. Second edition, revised and enlarged. 8vo, pp. 644. Philadelphia: J. B. Lippincott & Co. 1881.

The present edition of this excellent work gives abundant evidence of thorough and careful revision in every part. In all, nearly a hundred pages of new material have been added. The chapter on the anatomy of the skin, one of the most satisfactory ones in the book, has been largely re-written. Two new and excellent illustrations, drawn by Dr. Van Harlingen, have been added, showing the general anatomy of the integument and the minute structure of the epidermis. In this chapter also many points referring to the physiology of the skin are presented in a very clear and intelligible manner. New articles are added at more or less length on phosphorescent sweat, urticaria pigmentosa, uridrosis, impetigo, herpetiformis, dermatitis exfoliata, fungoid neoplasmata, perforating ulcer of foot, myoma cutis, dermatitis medicamentosa, and several other interesting cutaneous troubles. Additions have been made to almost every chapter in the original edition, and the work as a whole may now be considered a very complete and thoroughly practical exposition of the present state of dermatological medicine. The classification is that of Hebra, and this appears to be at once the most simple and rational that can be adopted for the thorough study of skin affections. Its excellence as a clear and practical therapeutical guide for the student is further enhanced in the present volume by the introduction of the various new remedies which have so freely abounded in the medical literature of the past three or four years. The work is well printed, and the illustrations are admirably executed.

How to Use the Forceps; with an Introductory Account of the Female Pelvis and the Mechanism of Delivery. By Henry G. Landis, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children, Starling Medical College, Columbus, Ohio. New York: E. B. Treat. 1880.

Professor Landis has given us a very practical, comprehensive, and interesting work upon the mechanism of labor and the use of the forceps. It can be read and studied with profit by every general practitioner.

A Manual of the Practice of Surgery. By Thomas Bryant, F.R.C.S., Surgeon to Guy's Hospital, etc. Third American from third revised and enlarged English edition. Edited and enlarged for the use of the American student and practitioner, by John B. Roberts, A.M., M.D., Lecturer on Anatomy and Operative Surgery in the Philadelphia School of Anatomy, etc. 8vo, pp. 1005. H. C. Lea's Son & Co. 1881.

Mr. Bryant's work has long been a favorite one with surgeons. As its name indicates it is of a thoroughly practical character. It is distinctly individual in that it gives the results of the author's large and varied experience as an operator and clinical teacher, and is on that account prized deservedly high as an original work. The style is necessarily condensed, the descriptions of surgical diseases and their treatment brief and to the point. The illustrations are well-chosen and the typical cases on the author's experience are full of interest and are of more than ordinary value to the working surgeon. The work may be considered as an *exposé* of British surgery from the standpoint of a thinking, practical surgeon who has used his clinical opportunities to the best advantage. The treatise does not aim to be an exhaustive one, to comprise a review of the literature of the different subjects treated, but rather as a summary of what Mr. Bryant knows—which is so far saying a great deal. The third London edition was somewhat enlarged, much new material was introduced and more than eighty new woodcuts were added. The general plan of the work remains the same, the subjects being for the most part amplified by text and woodcut.

The American edition is in a single volume of large size and handsome appearance, although the print is too small for the size of the page. The American editor has done his best to adapt the work more particularly to the wants of American surgeons. It can hardly be expected in the space alloted to him that he should be able to bring American surgery as a whole to its desired level as compared with British surgery. He has done his best, however, to advocate the claims of the surgeons of his own city, and so far his task has been well and conscientiously performed.

John Hunter and His Pupils. By S. D. Gross, M.D., LL.D., D.C.L., Oxon., LL.D., Cantab., etc. Philadelphia: Lindsay & Blakiston. 1881.

This neatly printed work of one hundred and twenty-three pages is the elaboration of an address delivered by Professor Gross before the American Academy of Surgery of Philadelphia. It is an interesting account of the life and character of Hunter, in which are contained many anecdotes illustrating his peculiar traits of character. To this biography is added sketches of several of his pupils. The whole is presented in the pleasant style peculiar to the author, and makes very entertaining reading. The volume contains a portrait of Hunter, copied from Sharpe's steel engraving of Sir Joshua Reynolds' picture.

Diagrams of the Nerves of the Human Body. By William Henry Flower, F.R.S. Third edition. Philadelphia: Presley Blakiston. 1880.

This is an atlas exhibiting in diagrammatic form the origin, division, connections, and distribution of the cranial and spinal nerves. It is admirably arranged, and will be of incalculable aid to the student of anatomy. Each of the large and beautiful plates is accompanied with explanatory text.

Drugs that Enslave: the Opium, Morphine, Chloral, and Hashisch Habits. By H. H. Kane, M.D. 8vo, pp. 224. Philadelphia: Presley Blakiston. 1881.

Dr. Kane has furnished the profession with a very useful and readable little work on the subject of the various habits. It opens with a heliotype of the Laocoön group facing the title-page, while after the preface is a table of statistics showing the great increase in the importation of opium to this country during the last decade. The whole is very well contrived to catch the attention of a casual opener of the book, whether he be a professional man or a layman; and his attention would be further fixed by the now well-known illustration of the Bellevue Hos-

pital nurse whose body was riddled with abscesses from the use of the hypodermic. This unfortunate has now, we think, fully expiated his folly by having served so long as an awful example.

Having bared the above little artifices on the part of the author, which are legitimate enough after all, we are inclined to give the book nothing but praise. It contains a large amount of information, collected with much labor, and presented in a systematic manner. The author's investigations of the chloral habit, his remarks upon the accidents of hypodermic medication, and upon the treatment of the opium habit, are particularly good. The subject of the chloral habit has not been investigated by any one, we believe, so thoroughly as by Dr. Kane. The London Clinical Society attempted the matter, but failed. We should judge from Dr. Kane's statistics that the chloral habit, though more or less prevalent, is not a very injurious one, or one that cannot be quite easily broken. The danger from chloral is not in the "habit" chiefly, but in the results that may occur from individual over-doses.

The author's style has improved since writing his first book. Some of his descriptions are forcible and vivid. We trust, however, that in any subsequent edition he will correct his inadvertence in referring to a lady patient who during the use of morphine "found her *virile* power in no ways impaired!"

Health Primers. The Heart and its Functions. New York: D. Appleton & Co. 1881. Price, 40 cents.

This is an excellent exposition of the physiology of the heart's action and its relations to health. As regards the latter point also there is considerable that is new and which will be likely to prove especially useful on that account.

Reminiscences of Dr. Spurzheim and George Combe: and a review of the Science of Phrenology from the Period of its Discovery by Dr. Gall to 1840. By Nahum Capen, LL.D. New York: Fowler & Wells. 1881.

This book is forty years old, in thought, though written less than a year ago. It has no scientific, and in our opinion no philosophical value. Those interested in biography may find something in it worthy of perusal. Spurzheim is to be esteemed greater than his theories.

On Certain Conditions of Nervous Derangement. Somnambulism—Hypnotism—Hysteria—Hysteroid Affections, etc. By William A. Hammond, M.D. 8vo, pp. 256. New York: G. P. Putnam's Sons. 1881.

Dr. Hammond's contributions to literature, especially those which like this book are of a popular as well as medical nature, are always timely and readable. Dr. Hammond deserves some credit also for furnishing to the public scientific explanations of many widely believed delusions. The present work is made up largely of a previous work on Spiritualism, etc., and of a short treatise on "Fasting Girls"—published, we believe, last summer. There is also incorporated a clinical lecture on metallotherapy and allied topics; and the subject of modern miracle-working is dealt with at some length.

Altogether there is a good deal of curious and interesting information in the book. Measured as a contribution to the philosophy or physiology of the subjects treated, it is incoherent, shallow, and without originality.

Syphilis and Marriage. Lectures delivered at the St. Louis Hospital, Paris. By Alfred Fournier, Professeur à la Faculté de Médecine de Paris, etc. Translated by P. Albert Morrow, M.D. 8vo, pp. 251. New York: D. Appleton & Co. 1881.

The translator of this work states in his preface that there is no work in the English language which treats of the relations of syphilis to marriage. This furnishes an excuse, if any were needed, for republishing the book in this country. The subject is truly one of the supremest importance, involving, as it does, questions not only of pathology, but of morality and domestic happiness. It is treated by Professor Fournier in a manner that is above criticism. Exhaustive clinical knowledge, discriminating judgment, and thorough honesty of opinion are united in the author, and he presents his subject in crisp and almost dramatic style, so that it is a positive pleasure to read the book, apart from the absolute importance of the questions of which it treats.

The opinions of Professor Fournier on the subject of syphilis and marriage have already been made known quite widely in reviews of the original work in French. We refrain, therefore, from giving any analysis of them now. Previous criticisms have shown a general unanimity of opinion with Professor Fournier, that syphilis is only, as a rule, a temporary bar to marriage.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 9, 1881.

Dr. T. E. Satterthwaite, President, in the Chair.

Dr. Willard Parker, Jr., on behalf of a candidate, presented a

"COMPOSITE TUMOR OF THE TESTICLE."

Dr. W. H. Porter, on behalf of a candidate, presented a specimen of

TRANSPOSITIO CORDIS, WITH ABNORMAL DEVELOPMENT OF THE ORGAN.

The President asked if the malformation was a common one, and Dr. Porter answered that it was not, and further remarked that the pulmonary veins sometimes rise from the descending aorta. In the specimen presented, they seemed to come from the ascending aorta, probably because there was only one ventricle and auricle in the heart.

The President said that this deformity is more rare than that in which there is one ventricle and two auricles.

FIBRO-MYOMA OF THE UTERUS.

Dr. R. Tauszky presented what seemed to be a fibrous tumor, removed from the uterus of a patient, twenty years of age, with the following history: She began to menstruate at the age of fourteen, and the monthly discharge was regular for about one year, when she began to suffer extremely from dysmenorrhœa, for which she consulted many physicians, but received only temporary relief. About two months ago she began to suffer from profuse menorrhagia and metrorrhagia, became very anæmic, and was obliged to remain in bed. Dr. Tauszky saw the patient in consultation with Dr. Strew, who had

diagnosticated retroflexion, as had Dr. Skene, of Brooklyn, some time previously, but the condition did not seem to explain the severe dysmenorrhœa and menorrhagia. After dilating the cervix a tumor in the cavity of the uterus was diagnosticated. The dilatation was increased, and the tumor was removed. But, despite the dilatation, Dr. Tauszky found it necessary to divide the tumor, and also incise the cervix before complete removal could be effected. It was attached to the posterior wall of the uterus, high up, and was so situated that it could easily escape recognition in an examination made with the uterine sound.

ANEURISM OF THE THORACIC AORTA.

Dr. W. H. Porter presented a specimen accompanied by the following history, furnished by Dr. J. A. Wells, house physician, and in the service of Dr. Alexander Hadden: P. T——, aged forty years, born in Ireland, single, and conductor, was admitted to the Presbyterian Hospital December 23, 1880. Family history good; intemperate habits. Had a chancre twenty years ago. Good health prior to two years ago, when a cough developed, which was paroxysmal in character, and continued until death. The cough had been accompanied by more or less mucopurulent expectoration, that had been at times tinged with blood. He never had any distinct hæmoptysis. Considerable dyspnœa, especially marked upon exertion. Persistent pain in the right side. No hectic. General health became impaired. Two weeks before admission all the above symptoms became aggravated, and were accompanied by high fever and general constitutional disturbance. Pain, dyspnœa, and expectoration were especially increased.

When admitted he was suffering from severe dyspnœa, with flushed face, but his temperature was nearly normal. His cough was paroxysmal, expectoration scanty and viscid. Moist râles over both lungs, anteriorly and posteriorly. Voice and breath heard, except over lower lobe of right lung. Dulness below right scapula, also bronchial voice and breathing. Heart-sounds very feeble; no murmurs. Pulse 140. Stimulants and diuretics were administered.

December 25th.—Patient slightly improved.

December 29th.—Dyspnœa less severe. Dry cups applied and stimulants continued.

Physical examination.—Over the superior portion of right lung the breathing and voice-sounds were nearly amphoric in character. The heart was carefully examined with a stethoscope, but no murmurs could be detected. The dyspnœa became so excessive that the patient could not lie down while in the hospital. No episternal pulsation.

January 3, 1881.—The patient coughed up four ounces of bright red blood. The hæmoptysis seemed to yield to the free administration of ergot.

January 4th.—At 3 A.M. the patient coughed up three ounces more of bright red blood. This hemorrhage also yielded to rest and ergot. The patient remained comfortable until 7 P.M., when another slight hemorrhage occurred, and he fell back dead.

Necropsy thirty-eight hours after death: Rigor mortis well marked; body well nourished.

Thoracic cavity.—The pericardium contained one ounce of serous fluid. Left heart hypertrophied; weight of organ, fifteen ounces. One of the segments of the pulmonary valve had a small hole through it; otherwise the right side of the heart was normal. One segment of the aortic valves had one hole in it, a second segment three. Both the mitral and aortic valves, as well as the aorta, showed evidence of acute inflammation by the deep congestion and numerous ecchymotic spots. At the base of the aortic valves there was marked atheromatous degeneration. The aorta, from the heart to its termination, was one mass of fatty and atheromatous degeneration. Near the aortic valves there were several cicatricial depressions. At the posterior and upper part of the transverse portion of the aorta there was a small aneurism. The aneurism encroached upon and dilated the commencement of the innominate artery, while the left common carotid appeared to be perfectly normal. The aneurism had ulcerated through the trachea at two points, one opening being between the fourth and fifth rings above the bifurcation, the second one higher. The aneurismal sac, not larger than a good-sized hen's egg, was partially filled with a clot, which had apparently at times acted as a ball-valve.

The left lung was deeply congested, and in the most dependent parts in a stage of hypostatic congestion; weight twenty-five ounces. The right lung would float in water, although the lower lobe presented the gross appearances of the third stage of pneumonia. Weight of right lung, forty-eight ounces. Spleen enlarged; weight nine ounces. Kidneys deeply congested; capsule non-adherent; weight eight ounces each. Liver enlarged; weight eighty-eight ounces.

Dr. Porter presented a second specimen with the following history:

CHRONIC ALCOHOLISM, MENINGEAL AND CEREBRAL HÆMORRHAGES, ANGIOLITHIC TUMORS OF THE CHOROID PLEXUS.

A woman of unknown age, but thought to be upwards of sixty years, was arrested for habitual drunkenness January 31, 1881. Having been taken to a police station, she became unconscious and an ambulance was accordingly sent for. Dr. Duffield, who then assumed charge of the case, found on examination that there was no evidence of intoxication, but his attention was directed toward a large ecchymotic spot over the right eye, and an extravasation in the tissues about the orbit. The patient was removed to the Presbyterian Hospital in an unconscious condition and died a few minutes after admission. At the necropsy, fifty-six hours after death, it was found on removing the calvarium, that the whole surface of the left hemisphere was covered by a blood-clot weighing eight ounces, and located between the dura and pia mater. Both ventricles contained bloody serum in excess, and their walls were the seat of small extravasations. The fourth ventricle likewise contained bloody serum in excess. There was a blood-clot within the substance of the pons, upon the right side. No fracture or fissure of the skull was found in connection with the clot. The occurrence of the multiple coagula was, therefore, regarded as the result of a general systemic condition, and violence was rejected as the cause of death. The rupture of several vessels in such cases has been observed in a number of instances. Unfortunately, there was little information that could be obtained which would throw light upon her previous condition.

The *contents of the thoracic cavity* appeared to be normal, the only organ having any noticeable lesion being the heart, which exhibited slight atheroma in the valves on the side.

In the abdominal cavity the organs were not mark-

edly diseased, the liver alone excepted. This was enlarged, fatty, and weighed eighty-seven ounces.

An interesting feature in the cranial contents was the presence of two tumors, one in each choroid plexus of the lateral ventricles. The larger was the size of a hazel-nut, yellow, streaked by blood-vessels upon the exterior, and having contents which seemed to bag out irregularly, much as a sack would that had been filled with large stones. On section of one tumor, the smaller, about half the size of the larger, there was a gritty sensation under the knife as if there were calcareous particles present, while there was much matter that appeared sebaceous. On microscopic examination it was found that the neoplasm was composed of a fibrous basis in which blood-vessels were very numerous, and contained concentrically formed granules, of various size, together with pigment, while cholesterine in plates was freely intermixed throughout the solid portions. It was not thought that the tumors had occasioned any symptoms.

The President remarked that these tumors are probably not sarcomatous, but simply fibrous tumors, in which there is a large development of blood-vessels. In connection with them are found these curious sand-particles, which have concentric markings and are probably calcified epithelial corpuscles in compressed balls, having the appearance of epithelioma. Again, the existence of cholesterine indicates a further retrograde metamorphosis of epithelial tissue common in this locality.

Dr. E. C. Wendt presented specimens taken from the body of a patient who died of

HODGKIN'S DISEASE.

They were accompanied by a history furnished by Dr. Haig, assistant house physician to St. Francis' Hospital.

J. B——, aged eighteen years, United States, single, plumber. Father died of cancer of the stomach; mother cut her throat while insane. About eighteen months ago the patient first noticed a small enlargement beneath his right ear. It was movable, rather hard, and painless. For six months it slowly enlarged, and then quite suddenly it rapidly increased in size, so as to soon occupy the side of the neck from the clavicle to the ear. From the median line this nobby tumor extended to the anterior border of the trapezius muscle. At this time he applied for relief at a clinic, and was there operated upon. It was stated that sixty-two enlarged lymphatic glands were removed from the lateral region of the neck, the patient being nearly five hours under ether. He was afterward removed to Bellevue Hospital, where he remained seventeen days. When discharged the cervical wound had nearly healed. At this time he noticed a small nodule below the inferior maxilla, and also several nodules above the clavicle on the right side. These swellings immediately began to increase in size, their growth being a very rapid one. The glands on the opposite side of the neck also began to enlarge. He entered Roosevelt Hospital, but was refused the desired operation; was next admitted to Bellevue, but Dr. Wood also refused to interfere. The glands continued to increase in size, the patient became intensely anæmic, at the same time losing flesh and strength. He was admitted to St. Francis' Hospital on November 17, 1880. At that time he had a hard nodular tumor, extending from the median line to the edge of the trapezius muscle, and from the lobule of the ear and the base of the skull behind and lower border of the inferior maxilla in front, to midway between the inferior maxilla and the clavicle. There were also several small movable nodules above the clavicle. He also had a tumor filling the supra-spinous fossa of the right side. In the right axilla there were several nodules. On the left side he had similar enlargements, as on the right side of the neck. There was no cough, neither dyspnœa nor dysphagia, neither interference with phonation nor respiration, and no pain. Patient was put on Fowler's solution and tonics, but did not seem to improve. A sinus that had remained from the operation continued to discharge. The tumors on both sides steadily enlarged. He grew more anæmic; still the appetite was poor. About December 10th his feet became œdematous, the urine showed albuminuria (fifty per cent.), and remained albuminous, ranging from thirty to seventy per cent. until death. Patient continued to grow worse. Glands beneath chin were quite soft, and seemed as if they were undergoing suppuration. Electricity was tried, but produced no effect. From this time until death he suffered great pain in the abdomen. He died suddenly on January 11, 1881.

[Dr. Howe added that for several days before death the patient suffered from dyspnœa like that seen in croup.]

Autopsy.—Abdominal cavity contains a small amount of serum. Spleen very much enlarged, its capsule thickened. On section there appear numerous round, yellowish white nodules. Its substance is abnormally hard, and the remnant of pulp is sprinkled with granules resembling sago grains. Treated with iodine, these granules assume a dark brown tint. At the hilum a large cluster of hard, lymphatic glands appears. Kidneys are very much enlarged, resembling "large white kidney;" some of the pyramids, however, are normal in appearance. The retro-peritoneal and mesenteric lymphatic glands are very much enlarged, especially the former. Pancreas, of abnormally firm consistence, appears to be hypertrophied. Lymphatic glands at hilum of kidneys are enlarged, forming a hard bunch. Left lung shows marginal emphysema and brown induration. Right lung in same condition. Liver is enlarged and very pale. Whitish nodules like those in the spleen are found throughout its substance. Stomach quite small. Inguinal glands are enlarged and hard. Axillary, supra- and infra-clavicular, mediastinal and bronchial glands, at the lesser curvature of the stomach, all participate in this universal increase of volume. Wherever lymph-glands occurred in the body they were found conspicuously enlarged. They had not a uniformly hard consistence; those beneath the jaw were especially soft.

Remarks.—"The blood of this patient was not examined during life, but on post-mortem inspection an increase in the proportion of the white globules was not found. It appears, therefore, that the case was one of so-called pseudo-leukæmia (Cohnheim), or better, Hodgkin's disease. Of the true nature of this affection we know but little. The progressive enlargement of lymphadenoid structures has led Trousseau to call the disease adénie. The essential lesions are similar to those of true leucocythæmia, and it is not easy to understand why in the one case the leucocytes are so enormously increased in number, whereas in the other their relative proportion remains quite or nearly normal.

"A remarkable feature of this case is the presence in the spleen of amyloid degeneration of the malpighian bodies, in conjunction with diffuse hyperplasia and the multiple occurrence of lymphadenomatous tumors. Microscopical sections show these

pathological conditions very beautifully. Granules of blood-pigment, variously tinted, brown, yellow, or almost black, are scattered in heaps throughout the new-formed adenoid tissue. In the liver the neoplasms have a structure identical with that of the splenic nodules. It has been described by Virchow as lympho-sarcoma. The evident malignancy of these cases perhaps justifies Billroth's appellation of these new-growths as "malignant lymphomata." Laughaus called the disease malignant lympho-sarcoma, which is a superfluous pleonasm. As regards the knobby tumors of the lymph-glands, which in some places appeared in confluent lumps, their cut surface in general presented the ordinary encephaloid appearance of most hyperplastic processes involving these organs. It is a fact deserving of mention, that their gross appearance was not altogether uniform, the variations corresponding to histological differences of structure. Most of the glands were hard, firm, rather inelastic. These were found to show a comparative preponderance of the new-formed connective-tissue reticulum over the accumulated small round-cells. On the other hand, the softer glands showed such an overabundance of lymphoid corpuscles, that all other structures were veiled by their presence. It seems that the older collections were the harder ones, and the most recent ones those of softest consistence. But this point was not clearly settled. The latter had certainly grown most rapidly. I am not aware that sago-spleen is a frequent, or, for that matter, even a rare concomitant of Hodgkin's disease. Perhaps the prolonged suppuration following the surgical interference may be considered an etiological factor in bringing about the amyloid degeneration.

"As for the many different names the disease has received, they indicate the unsettled condition of our knowledge regarding it, this being in part due to the relative paucity of well-observed cases of this kind. It may be mentioned that Schulz (*Arch. der Heilkunde*, 1874), proposed the term dermoid carcinoma for the characteristic neoplasms of this affection. This is a pathological term of questionable propriety. From a clinical standpoint Wilks has coined the word lymphatic anæmia. Gowers and Ranvier have termed the disease lymphadenosis; we might with equal justice speak of scrofula as lymphadenosis. In view of the difficulties in the way of choosing a term which may be satisfactory in all respects, it seems best to retain the non-committal expression—"Hodgkin's disease."

THE PRESIDENT also presented specimens taken from the body of a patient who died of

HODGKIN'S DISEASE.

They were accompanied by the following history, furnished by Dr. R. T. Bang, house physician.

HODGKIN'S DISEASE WITHOUT LYMPHATIC TUMORS IN INTERNAL ORGANS—OCCLUSION OF ILIAC VEIN.

THE PRESIDENT then presented the cervical, inguinal and retro-peritoneal glands in a case of the above disease, with the following history, furnished by Dr. Bang, house physician to St. Luke's Hospital.

B. F——, aged eight years, of German parentage, was admitted July 17, 1880. The mother stated that three years previously she first noticed a lump the size of an almond behind the child's right ear. At the end of a year she thought there was only a single tumor, now the size of a small orange. At the end of the second year this mass had reached half-way down the neck. More recently a large number of smaller tumors the size of chestnuts appeared.

On examination, the following points were noted: On the right side of patient's neck is a tumor measuring 5½ inches in length by 4 in breadth. It is made up of distinct nodules varying in size from a cherry to a hen's egg. The smaller lumps are on the borders, and are quite movable.

Below, the mass hangs over the right clavicle. Above, it is limited at the insertion of the left sterno-cleido-mastoid muscle. It reaches to the median line anteriorly and posteriorly.

In the left groin there is also a tumor which is the size of a small egg, and made up of three distinct nodules. In the right groin is a single movable lump the size of an almond. All the enlargements in the groins have appeared within the past five months. Further points noted by the attending physician were as follows:

The glands forming the central portion of the tumor in the neck are not movable one upon another, but form a conglomerate mass.

The smaller glands included in the mass, and located on the periphery, are movable and have less consistency. The skin covering the mass is everywhere freely movable. No soft glands anywhere in the mass. No enlargement of tonsils. No stomatitis. No enlargement of follicles at the root of the tongue. No indications of pressure upon the œsophagus, trachea or recurrent laryngeal nerve. A single enlarged gland in the left axilla. There is a conglomerate mass of glands in the left groin the size of a hen's egg, and a single gland of the size of a walnut in the right groin.

Physical examination fails to make out any enlargement of the liver or the spleen. The belly is protuberant. No enlargement of the epitrochlear glands. The veins over the upper portion of the chest on both sides are distended. Examination of lungs negative. Heart in natural position—sounds normal. All visible mucous membranes anæmic. Patient has had no diarrhœa or vomiting.

October 5th.—The tumors have grown softer under the oleate of mercury. The sternal end of right clavicle is movable in its articulation.

November 29th.—Patient has been having the tumors daily injected with Fowler's solution (from 1 to 10 minims). The blood is extremely watery and pale in color. No bad effects from use of arsenic.

January 2d.—Without warning the patient was taken with choreic movements of the left arm. These continued all day. Previous to this occurrence the patient had no alarming symptoms. She never complained of suffering in any way, yet had no inclination to romp and play with the other children. Her face was extremely anæmic and waxen in appearance.

Examination of the urine on several occasions gave negative results.

The choreic movements of the left arm and occasional general convulsions continued for two days, at the end of which time, while in one of the latter, she spat up some purulent fluid, and expired, January 3, 1881.

At the post-mortem examination there was found great emaciation, anæmia, and œdema of the feet; the glands implicated were found to be the left cervical, superficial and deep, and the axillary to a slight degree; and on the right side the lumbar sacral iliac and inguinal and mesenteric. The submaxillaries, sublingual, parotids, the liver, spleen, kidneys, and intestinal tract contained no nodules, no special variation from the normal seen in the organs, except as

already mentioned, if we except a purulent bronchitis. It was noticeable on removing the lumbar and iliac nodules that they completely encircled the vessels, occluding the right common iliac and portions of the internal and external iliacs. On exposing the occluded portions, they were found filled with a clot which at one point had broken down into a puriform fluid.

Weight of child, 30 pounds 10 ounces; liver, 1½ pound; right kidney, 4½ ounces; left kidney, 5 ounces; spleen, 3½ ounces.

Usually the nodules were separated by a more or less well-marked septa; but sometimes they were agglomerated together. In sections of the growths they were quite uniformly pinkish white in color, and soft; some had indications of caseation at their centres, though this was infrequent. On microscopic examination they gave the appearances of lymphatic tissue, in which the corpuscular elements were very numerous and the framework slight.

The President remarked further, that it was not always easy to distinguish this disease from splenic leucocythæmia, because in Hodgkin's disease, as now described by English writers, the spleen is enlarged in a small proportion of the cases. He should prefer to base his diagnosis in such cases on the occurrence of these peculiar glandular enlargements, especially when in the cervical region, and if they showed a tendency to coalesce; other important symptoms were progressive emaciation and anæmia. It might be difficult to decide as to the blood unless the hæmatometer were used. In this case there was a diversity of opinion, perhaps because no one had used the instrument. He would certainly expect a diminution in the red corpuscles, but less frequently an increase in the white.

Dr. Sell referred to a case in which a boy, twelve years of age, had an enormous enlargement of the cervical lymphatic glands, the glands in the right axilla and left groin, and also had bronchitis with chronic pneumonia, and had had diarrhœa. His blood had not been examined.

CANCER OF THE RECTUM.

Dr. J. W. Howe presented a specimen taken from the body of a man upon whom he had performed lumbo-colotomy in November, 1880. H. L——, sixty-one years of age, German. Family history unimportant. Never had rheumatism or syphilis. Had typhoid fever fourteen years ago, and was sick two months. Nine months previous to admission to the hospital the blood and fæces escaped from the anus at the time of micturition. He also suffered from tenesmus, and with each stool lost considerable blood. This condition of affairs continued with loss of flesh and strength, and three weeks previous to his admission he was unable to evacuate his bowels even by the use of cathartics and enemata. The calibre of the rectum was closed entirely by the cancerous mass. Two days after admission, Dr. Howe performed lumbo-colotomy according to Bryant's method, which was followed by relief from pain and all the distressing symptoms from which he had previously suffered. The patient died February 6, 1881.

Dr. Geo. F. Shrady asked if there was any discharge of fæces per rectum after the operation.

Dr. Howe replied that there was. He further remarked that in one hospital the operation of lumbo-colotomy was refused, and complete extirpation of the rectum was proposed.

Dr. Briddon regarded extirpation as a very dangerous procedure, and thought that the only safe method of offering relief was in lumbo-colotomy. He then referred to a case in which he performed lumbo-colotomy for stricture of the rectum in 1879, and the patient yet remained well. He thought it was a common result for the stricture to gradually disappear, especially if of syphilitic origin, after the fæces began to pass through the opening in the loin. But he never saw a case in which fæces passed through the rectum beyond two or three weeks after the operation.

Dr. Howe said that in his case fæces passed through the rectum during the last three weeks of the patient's life, but he believed it to be due to the sloughing of the cancerous mass.

CONCEALED UTERINE HEMORRHAGE.

Dr. Van Gieson presented a fœtus and placenta removed from a primiparous woman twenty-seven years of age, who was taken in labor on January 30, 1880. At about 10 P.M. she began to have inefficient pains at long intervals, and at the first vaginal examination he noticed that the woman had an anæmic appearance, frequent and rather weak pulse, and, when she raised her head from the pillow, there was a tendency to syncope. There was no external hemorrhage. Pregnancy had advanced to between the seventh and eighth month, and from the fact that she had been under his care during the last two years, and he had seen her frequently with similar symptoms due to neurasthenia, he was somewhat misled with regard to diagnosis. He returned to his patient at about 1 A.M., January 31st, and then found that the symptoms of debility had increased and the pulse was 120, the tendency to syncope very marked, and the pains still irregular and inefficient. At the second examination he found the os dilated sufficiently to admit the index and middle fingers, and *dilatable*. There was no external hemorrhage. His diagnosis was concealed uterine hemorrhage, and he determined to dilate the cervix as quickly as possible and deliver the woman. The dilatation was done by a circular, sweeping motion of the fingers, and at the end of an hour and a half he was able to introduce the forceps. In the meantime the pulse increased in rapidity and also the tendency to syncope. The uterus seemed much larger than would be expected from the size of the fœtus. The uterus, through the abdominal walls, had a distinct, boggy, doughy feel, and there could not be obtained, by the most careful examination, any trace whatever of fetal sounds. He delivered the woman as rapidly as possible with the forceps, the placenta followed immediately, and with them not less than half an ordinary pailful of dark, grumous blood. By kneading the uterus it was made to contract. He gave the woman whiskey, ergot, and opium, and at the end of an hour and a half she was left in comparative safety.

The child was white as marble when delivered, and the placenta showed distinctly where the detachment occurred. It was the third case of this kind which he had had, two of which he had reported to the society. The importance of early diagnosis could be readily seen, and the diagnostic points upon which he would rely were, the marked anæmic condition of the patient without external hemorrhage, the tendency to syncope, the doughy feel of the uterus, the slow and inefficient labor-pains, and the absence of fetal heart-sounds. His patient was doing well. The only paper which he had seen that treated the subject exhaustively was that published by Dr. Goodell, of Philadelphia, in the *American*

Journal of Medical Sciences, some seven or eight years ago.

CARIES OF THE ELBOW-JOINT—AMPUTATION.

Dr. C. K. Briddon presented carious bones of the elbow-joint removed by amputation from a patient fifty-two years of age, single, a sailor, intemperate, and syphilitic, who was admitted to the Colored Home, January 17, 1879. He had been previously treated for arthritis four months, left the hospital improved, and resumed his occupation. The joint again became inflamed, suppurated, and was opened, and he was readmitted December 27, 1880. The condition of the joint was such that exsection would probably have been followed by osteo-myelitis, and amputation seemed to be the only admissible operation, and accordingly it was performed January 31, 1881. For two or three weeks before the operation the patient's temperature had been high, sometimes 104 and 105 F., but the day before the operation it fell to 100° F.; and advantage was taken of the remission and the amputation performed. Immediately after the operation his general condition began to improve.

FIBRINOUS CAST OF THE EDGE OF THE TONGUE.

Dr. L. Elsberg presented a fibrinous cast of the edge of the tongue, that formed within twenty-four hours, independent of the appearance of pseudo-membrane in any other part of the oral cavity. When he removed it the tongue was swollen, but not ulcerated. There was an ulcer in the pharynx. There was no history of syphilis. A second membrane formed within twelve hours, but it was not so thick as the first. When the cast was removed the mucous membrane was not divested of its epithelium, but it showed bleeding points. The new formation was elevated above the surrounding mucous membrane, and was limited to the edge of the tongue.

The President presented a specimen with the following history:

CARCINOMA OF THE PANCREAS—OCCLUSION OF THE DUCTUS COMMUNIS—CAVERNOUS METAMORPHOSIS OF THE LIVER.

J. McE——, twenty-three years of age, single, stationer, was admitted into the Presbyterian Hospital August 9, 1879. The patient gave the history of a young man who had not suffered from any inherited or acquired disease. His first marked symptoms were those of pain in the epigastrium about one year before admission to the hospital. Soon after these symptoms set in he was taken with vomiting, and began to emaciate and rapidly lose strength. Jaundice followed, with œdema of the legs. The bowels were now very much confined. After a while the jaundice disappeared, but the pain continued. Just before admission his symptoms suddenly became aggravated, and the stools had a clayey color.

On admission, in addition to the symptoms just noted, purpuric spots were observed over the lower extremities, and oozing of blood from the anus. Dyspnœa and pain were soon marked. The patient died on the following day in a comatose condition. The urine had not indicated any renal difficulty, though it contained blood.

Autopsy by Dr. W. H. Porter, twenty-one hours after death. Body deeply jaundiced. Lower extremities œdematous. Thoracic cavity: the pericardial sac contained one ounce of clear, straw-colored, serous fluid. The ventricular cavities were distended with fluid blood. Valves free and sufficient. Heart-substance slightly fatty; weight of organ, ten and one-half ounces, which was deficient, considering the size of the man. Right lung entirely free from pleuritic adhesions, but the left was firmly bound throughout to the chest-walls and diaphragm. Lungs œdematous, otherwise normal. Weight of both, thirty-two ounces. *Abdominal cavity:* spleen firm and very dark in color; weight, nine and one-half ounces. *Kidneys* intensely congested and stained yellow, probably with bile-pigment. Capsules slightly thickened and adherent; weight, five and five and one-half ounces each. The *stomach* showed slight evidence of chronic gastritis. When the duodenum was opened the ductus communis choledochus was found absolutely occluded by a growth, which surrounded the bile-duct, and was posterior to, but did not involve the gut. The whole portal circulation was to a considerable extent interfered with by the new growth pressing upon the main trunk. The common bile-duct above the occlusion was enormously distended, being at least one inch in diameter. The gall-bladder, also, was greatly distended, and contained about twelve ounces of bile. The liver was also distended with blood, and stained yellow by biliary pigment. Weight, one hundred and eight ounces, or more than double the normal.

No abscesses were found at any point. The head of the pancreas was the seat of a new-growth about the size of a small orange. This new-growth lay behind the duodenum, and had grown in such a way as to completely encircle the ductus communis choledochus and occlude it. The common duct seemed to end in the centre of this growth.

Microscopic examination gave the usual evidences of scirrhous carcinoma. The greater portion of the liver was the seat of cavernous change. It looked and felt like a sponge. By using a colored injecting fluid, and syringing through one of the smaller vessels of the liver, the cavernous tissue was injected. It was not easy to determine which vessel communicated with this new tissue. At any rate, injections through the portal and its tributaries did not reach the cavernous tissue, and other injections, through the hepatics presumably, were no more successful. As all the vessels were much dilated, it was difficult to decide precisely which they were.

This change in the liver had not produced any marked hepatic symptoms during life, though nearly the whole gland was affected, a fact which probably made the specimen a unique one. It was also to be observed that, notwithstanding the occlusion of the common duct, there were no abscesses of the liver, as are frequently observed in such cases.

Dr. John C. Peters remarked that one case of cavernous transformation of the liver had been reported to the society, and that its history could be found on pages 25 and 26 of the third volume of the transactions.

The President presented, by card, a specimen of ROUND-CELLED SARCOMA OF A KIDNEY, FROM A COW.

The society then went into Executive Session.

Dr. André Poulen, a most promising young physician of Paris, was recently murdered by the *concierge* of the house where he resided. The murderer had just been discharged by his landlord from his position as *concierge*, and he attributed his discharge to the influence of Dr. Poulen. The murdered man had just ended a four years' course in the Paris hospitals. He had also won a prize medal and had been appointed *chef de clinique* under Prof. Hardy.

MEDICO-CHIRURGICAL SOCIETY,

LOUISVILLE, KY.

Stated Meeting of January, 1881.

DISCUSSION ON PLACENTA PRÆVIA.

AT the previous meeting of the society, a case of placenta prævia having been reported by Dr. Clemens, it was then decided to devote the present session to the discussion of that subject. The case, as stated by Dr. Clemens, is as follows:

I was called to see a woman seven months pregnant with her fifth child. She had been suffering from hemorrhage for two weeks, but had lost no considerable amount of blood until the night before I was called to see her. In the afternoon, some two or three hours before I was called, she had a fearful flow, and was thought to be dying. On examination I found the os dilated to about the size of a silver dollar and the placenta protruding. I sent immediately for ergot, but before it came I had succeeded by artificial means in establishing uterine action, and by introducing two fingers I dilated the os, and as soon as the ergot arrived she was given a drachm of it and I soon succeeded in delivering her. An unfavorable prognosis as to her recovery was given, and I explained to the family the danger of septicæmia from the drain of the lochia over the mouths of the vessels where the placenta had been attached. I ordered ergot to be procured and given in case she should suffer an attack of hemorrhage, and viburnum prunifolium for slight hemorrhage, and also McMunn's elixir to be given night and morning. I repeated the instructions two or three times to a stupid nurse, and placed the bottles separately on the mantelpiece—one at each end and one in the middle. She succeeded in getting them mixed, and gave the ergot two or three times, although there had been no hemorrhage. When I returned the next morning the lochia was arrested, and I was not able to restore it. I believe the imprudent administration of the ergot had much to do in bringing about the fatal result which followed. Without it the drain might have been sufficient to prevent septicæmia.

I detached the placenta as rapidly as possible, as the best means of arresting the hemorrhage.

DR. LARRABEE.—The point of the greatest interest and practical bearing to the physician is this which Dr. Clemens has referred to—the detachment of the placenta. We find, according to statistics, that the mortality under the older management was much higher than at present. In attempting to deliver without this procedure we have, according to English statistics, a mortality of 33⅓ per cent. to the mother and of 65 per cent. to the children. While, after the plan of Simpson, going in boldly and detaching, the mortality is reduced to one in fourteen to the mothers, while the mortality to the children is increased to 69 per cent.

Naegley gives the proportion of cases occurring in practice as 11 to 600. It is somewhat strange, this being the case, that I have attended four cases at full term, and this winter saw one case at the seventh month, the result being that, out of the four cases at full term, two were lost and two were saved. The last case was saved, of course, and had I sooner seen one of the cases mentioned as fatal, I think I would have saved it. A midwife was in charge for two days, and on the occurrence of hemorrhage a physician was called in, who tamponed the vagina, and upon being recalled made a hasty visit, prescribed some ergot, and left, after which he never could be found at home when wanted. I saw the case at the urgent request of the parties, with the knowledge that another physician had been in attendance. I found the woman in articulo mortis, sitting up in bed with a face white as marble, there being a pool of blood on the floor. The first thing done was of course to put her in the horizontal position; she gasped several times and finally regained respiration, breathing tolerably well. I placed my hand in the vagina, introduced my finger into the os, and made a partial detachment; then, with a piece of ice as a wedge, completed it and delivered the child, but the woman died as it emerged from the vulva. The other fatal case was lost by reason of the hemorrhage the woman had suffered for three months, which from her account, was excessive. When she came into labor she could not lose, without compromising her life, six ounces more of blood. She had a fluttering heart when she commenced to have the pains.

The other two cases Dr. Thompson saw with me. Being prepared for these, I took a Davidson's syringe and—using ice-water—Dr. Thompson manipulated the syringe while I directed the nozzle of it, detaching the placenta. As soon as it was delivered the uterus contracted firmly upon my wrist. I met with little difficulty, however, in getting hold of a foot and pulling it down, and at the completion of the delivery the woman had lost but little blood—not so much as the day previous from the dilatation.

In the case delivered at the seventh month the hemorrhage began at the fourth month, and the bleedings were mistaken for menstrual periods. When I was called I placed her in the horizontal position, and kept her so, using the viburnum three times a day. The hemorrhages, however, became more severe, and I was called to her one night with profuse hemorrhage, when I found it was not a central attachment, but a flap; I could feel it distinctly. It seemed to have been detached and rolled upon itself. In this case the mother made a good recovery. The child breathed a few times, but died. This mode of using the syringe is not original with me. I read it long ago in Galliard's journal, when it struck me as being sensible, and under similar circumstances I would use it again.

DR. THOMPSON.—I had one instance of this kind six or seven years ago. The case was one of partial placenta prævia only. The hemorrhage was not very severe, but the discharges after a time had a fetid odor, which induced me to give an unfavorable prognosis. In spite of all efforts to ward it off, pueperal fever set in two days after labor and terminated the case fatally.

DR. HOLLOWAY.—I must confess I am not posted as to any new plan of treatment of placenta prævia. I have had three cases at nearly full term—the children viable—and I have saved all of the mothers, two of the children being dead before I was called; in the the other case the child, at the seventh month, lived three days. My plan has been—I judge from what Dr. Larrabee says—the old plan of introducing my hand and arm, and as soon as possible getting hold of the feet of the child, allowing my hand and arm to act as a plug to prevent hemorrhage until I can get the child down to take its place. With reference to Dr. Larrabee's partial occlusion of the os, I would say we do not call those cases placenta prævia alone, but placenta prævia modified. In these cases it is the simplest thing in the world to pass the hand beside the placenta, and turn the child

and deliver. Waiting to detach the placenta, it seems to me, would increase the danger. Again, it is not always that the doctor has an assistant to labor with him. In the partial placenta prævia the plan strikes me as unnecessary, and altogether it shocks me. If you detach the placenta first you are going to lose the child, and it seems inevitable that, just in proportion as it is detached, hemorrhage will be severe; while if it is still attached a little, it offers more hope for the salvation of the child. It appears to me, sirs, that I would pay little attention to new plans of procedure when I found it necessary to put my hand in there to stop the bleeding. It must be a large vagina that my arm will not fill up, and I know they cannot bleed so very much so long as my arm is in there; and so soon as my arm is removed, I take care to have the child substitute it. Professor Williams called me to the country to see a case he had been watching for some time. I advised him to introduce his hand and deliver the child. In doing so he penetrated the placenta, and the woman did not lose enough blood to affect the pulse. I must say I am free to condemn this procedure of waiting to detach the placenta rather than to turn and deliver.

Dr. Bailey.—There are some questions of interest in the management of these cases, of which I would like to speak: the proper time to interfere, and whether it is proper to give ergot in cases of this kind at full term. I have my views as to the propriety of administering ergot for the control of hemorrhage in these cases, inasmuch as in the majority of cases relief comes by turning, which manipulation will be somewhat compromised or hindered by the influence of ergot; and moreover, whether by uterine contraction hemorrhage is controlled, or whether it is not rarely increased. The effect of uterine contraction to complete dilatation would be to separate the section of the placenta next to the os, and I see no reason why by each contraction hemorrhage should not be increased. I would hesitate, then, if I had a case of placenta prævia, to administer ergot, because I would expect to have to turn the child and deliver, and I believe that in such cases more can be accomplished without than with it.

The intention, I think, was first, in this method of detaching the placenta for the purpose of controlling hemorrhage, to remove the placenta by means of that procedure from that portion of the os least covered by it, leaving it attached elsewhere with the view of prolonging the life of the child. I was astonished to hear that the total detachment of the placenta before delivery does not increase the mortality to the children over four per cent. I do not see how it is possible to save 31 per cent of children where the placenta is brought away before the child.

I would like to speak of one other point, and that is at the present the practice of allowing these cases to go to full term. I know that a practitioner has been criticised by many of the best and ablest practitioners and obstetricians in the city, because he permitted a case to go to full term, and then, by plugging the vagina and waiting for dilatation, that he lost both woman and child. It is held by those who criticised, that the woman ought to have been delivered as soon as the child was viable; and I think myself that the sooner delivery is accomplished after that period is reached, the less the liability to death of the mother. In partial placenta prævia the detachment of the flap causes the hemorrhage to stop, whether labor comes on or not, and that I regard as good practice; but I cannot indorse that practice which would go on to the complete detachment. It is very seldom an attachment completely central will be found but the edge on one side will be reached soonest. When it is completely central I think it not only possible, but good practice, to go right through it and deliver the child, or detach first and then deliver.

For my part, I do not think the salvation of the child is at all comparable with that of the mother. When it comes to a question between the child and the mother I would have no hesitancy; and if I had a case now of placenta prævia, I would, if possible, conduct it on to such time as the child was viable and then deliver. I would assume that responsibility just as soon as there was a prospect of saving the child, but I would not feel warranted in giving ergot previous to delivery.

Dr. Senteny—I would like to say a word in reference to the statistics of cases of placenta prævia compared to the whole number of cases of labor. I wish simply to say this: that statistics upon this subject, as upon most others, are, in my judgment, unreliable. I arrive at this conclusion, however, from my own experience. I have been practising about forty years, and I suppose that in about twenty years of that time I had upon an average fifty obstetric cases per year, and the other twenty, perhaps twenty cases each year, making in all about 1,400, and in all that number of cases I have seen but one of placenta prævia complete. I have seen two others—possibly three—where there was a flap of the placenta covering over the os, but which did not interfere particularly with the result of the case. There was some hemorrhage in this case; though not enough to endanger the life of the child or the mother. In the case of central attachment, both the mother and child died. This occurred, however, in my early practice, when I was a little under the influence of older men, and being called to the case because another physician, who was the family doctor, could not be obtained. The case had gone to nearly full term and the flow was very alarming. I tamponed, as was the practice in those days, and sent for another physician, who had seen a great deal of obstetric practice. When he came he said I could do nothing but wait. I told him then, that I thought death would be the result of waiting. "Well," he said, "you can't do anything but wait." He stayed an hour or two and left. Being called to the case under those circumstances, and not feeling that it was my own case, and having the opinion of this man who had had a great deal of practice, I felt my way hedged in, and I did wait. Labor-pains set in; the head came down and advanced tolerably rapidly, the placenta preceding the head, and both placenta and child were delivered while the woman was yet alive; but she was so much exhausted from the loss of blood that she also died.

Should I have another similar case, I would adopt the expedient spoken of by Dr. Bailey. In speaking of the little value of statistics, I base my opinion wholly upon my own experience; but of course I do not intend to set that up in opposition to that of men who have had perhaps five times as much experience. I am inclined to think, however, that every case where there is partial attachment of the placenta attended by hemorrhage, has been called placenta prævia.

Dr. Clemens—I wish to say that, in speaking of the treatment of placenta prævia, I had reference only to the case I had in hand at seven months, with an attachment almost central. The woman was thought to be dying when I came. The os was dilated to about the size of a dollar, and it was impos-

sible for me to force my hand and arm in there; and as to perforation, I do not believe that plan is practicable in even a large per cent. of cases. If it is a central attachment it is exceedingly difficult to go through near the cord, where the membranes are much stronger than elsewhere, and reinforced also by the umbilical vessels. It does not occur to me as being a practical plan, though it may serve in some instances.

I have been impressed with the value of a treatment I saw reported in the proceedings of the Obstetrical Society of Cincinnati. I have forgotten the name of the author of the paper, but he reported most excellent results in two or three cases of placenta prævia by the injection of Monsel's solution of iron, which completely and at once arrested the hemorrhage, and thus enabled him to conduct the cases to a successful termination, both as respects the women and the children. I do not remember whether they were central attachments or not; my impression is that the os was covered, and it struck me as being a valuable method of treatment. I concur in the opinion that the nearer to full term the case can be conducted, the better. I do not see how anything can be gained by inducing labor prematurely.

THE CHICAGO BIOLOGICAL SOCIETY.

Stated Meeting, February 2, 1881.

W. S. Haines, M.D., President, in the Chair.

IS THERE AN ERUPTION IN DIPHTHERIA?

Dr. Lester Curtis reported a case of albuminuria in a child, ten days after an attack of sore throat. Diphtheria was present in the vicinity. Similar cases recurred often last winter. Were they cases of diphtheria?

Dr. H. M. Bannister thought they were cases of scarlatina without eruption.

Dr. H. M. Lyman said such cases were common in epidemics of scarlatina, but the eruption is sometimes overlooked by the physician; neither is it a necessary concomitant.

Dr. Curtis remarked that his case could not be referred to scarlatina: there were none in the neighborhood, and they did not give rise to any such case afterward.

Dr. Lyman said that cases of scarlatina do not always spread the disease, even among children that sleep together.

Dr. Bannister referred those cases to a *hybrid form* of scarlatina, not to be confounded with roseola or measles; yet that would not protect the patient from a subsequent attack of scarlatina.

Dr. Curtis again remarked that he had seen such cases in connection with epidemics of diphtheria. That he asked if albuminuria may not be a sequel of diphtheria, or of a common sore throat.

Dr. Lyman said that might be the case sometimes, and that there was some connection between mild and diphtheritic sore throats.

Dr. Roswell Park alluded to the activity of the scarlatina virus, which he had seen spread despite any precaution. He referred to cases which he called *pharyngitis with eruption*, not feeling justified in calling them scarlatina. He asked if an eruption can accompany diphtheria? which fluids in the body contain most contagious elements? what symptoms will justify the name scarlatina?

Dr. Lyman answered, saying that the diagnosis could not be positive if the case under consideration could not be traced to pre-existing cases, unless the albuminuria and rheumatism were present as well as the eruption. He never had seen an eruption in a case of diphtheria. It is doubtful which discharge is most poisonous—probably that emanating from the organs most affected.

Dr. Davis spoke of an epidemic of diphtheria in Columbus, O., some years since, in which mild attacks had been followed by albuminuria.

The society proceeded to a discussion of a paper on

THE GERM THEORY,

read before the last meeting by Dr. H. Gradle.

Dr. Curtis said every one should be on his guard against that theory, because it had become a fashion, and was likely to run into excesses. Some contagious diseases contain no bacteria, as, for instance, vaccinia, the particles of whose virus are all dissimilar, do not at all resemble bacteria, have the amœboid movement, when *micrococci* move by vibrations, and are nothing but degenerated bioplasm. A plausible objection was that many diseases referred to vegetable germs were caused by the irritation of those on the animals attacked, while the latter would recover as soon as the irritating parasites were removed. Another point: he coul dnot believe that bacteria had been isolated and cultivated. That during such a process there might have been invisible germs or substances accounting for the symptoms subsequent to an inoculation with the solutions. He said there was the shadow of a doubt in Pasteur's experiments, while, besides the results obtained with fowl-cholera, and with the silk-worm disease, all others were devoid of accuracy, and did not command confidence. For his part he was not convinced, and supposing the question settled in the affirmative in regard to a few diseases, there was no reason to ascribe others to the same cause.

Mr. R. S. G. Paton, chemist, observed that we cannot produce life in laboratories; that it is impossible thus to produce digestion, and thereby obtain living cells; that the cultivation of bacteria in living tissues, he thought, would give totally different results from those of Pasteur. Besides, there is a *basis of life*. The same fluid in plants goes to form a twig, a leaf, or a fruit, but how is that accomplished except through the intervention of germs or ferments? In the same manner in animals, one fluid goes to form bone, muscle, and nerve. But the ferment or germs which induce the change of the liquid into the substance of an organ may be deficient or in excess: as in phthisis, in which there is an excessive growth of bone. In either case, the equilibrium of healthy life being destroyed, a disease is the result. According to that theory, the lack of a ferment, or the deterioration of one, might account for many diseases.

Dr. Lyman defined germ diseases a "class of diseases produced by organized beings growing and multiplying in an animal" in the manner of parasites. There is no doubt as to the existence of parasitic diseases of that form, and such is anthrax. But only a few of them have been demonstrated, and we generally refer the rest to ferments. Some think the action of these is catalytic, acting through their mere presence. Yeast fungi act that way in the fermentation of sugar—at least that view is held by many—and it is a fact that the greater portion of the alcohol is formed outside the parasite. Its presence more than its growth is the cause of the fermentation; which, however, does not take place with healthy, but with diseased yeast-cells. This fact throws much light on the cultivation of hay bacteria: the virus,

innocuous at first, becomes poisonous in the process of cultivation. From this we might infer that those diseases depend upon the presence and growth of bacteria, though they are not their product. These facts being admitted, would bring more accordance between the views of many authors, which seemingly disagree and at the bottom are the same. In anthrax the disease does not depend directly on the bacterium, but on the changes caused by the latter in the fluids of the body, through its presence acting like a ferment to modify healthy nutrition.

We may well imagine a living cell undergoing some modification, and thereby becoming capable to cause a disease which would end as the cell would resume its normal condition. Cell-life is unquestionably influenced by ferments. The glands of the stomach produce organized cells—pepsine—which will transform food into peptones, with which they go to modify all the cells of the body, some of these again becoming gland-cells. Thus the same form returns after a while. In hydrophobia the cells of certain glands become a virus, and this, in a second animal, occasions a similar change in the gland-cells. It is a question whether bacteria or accidents of nutrition are the prime cause of the disease under consideration.

Germs exist in all living bodies; why is not their alteration accountable for the disease of the body at large, as well as for a recurrence of the disease through generations, since they may resume their normal form, or return to a former unhealthy modification? Thus, an abnormal change will account for septicæmia, while there is no reason to refer it to extrinsic agents; a ferment has simply originated in the body from normal cells undergoing a change. It is unnecessary to avoid germs through disinfection, and Lister's method of dressing wounds is a "badge of ignorance." The bacteria in the air may be quite harmless, while a morbid action in the fluids of the wound may, through resorption, give rise to the constitutional symptoms, spray or not. In proof, cases treated according to Lister's method have not done much better than others. The care bestowed on the wound keeps the cells in vigor, and thus cleanliness accounts for the benefits of that method which will be soon abandoned.

Mr. Paton asks if it could not be that germs which would not feed on normal blood, might do so when the latter was diseased. Thus it would not be the condition of the atmosphere, but that of the living cells, in wounds that would hinder healing. May not carbolic acid prevent the cells from contamination by bacteria, cutting out the latter?

Dr. Lyman said that if the liquids of the wound are prevented from assuming unhealthy action, or if a free exit of discharges is secured, there will be no resorption determining disease. Carbolic acid acts in that manner. It has the disadvantage of diminishing the vitality of cells through anæsthesia, and retards healing. There are many antiseptics superior to it.

The President called attention to the fact, as yet overlooked, that a liquid, after a removal of its germs through filtration, is incapable to inoculate the disease. The claim is thus for bacteria, not for their secretions. But that the fluid is innocuous is not conclusive. Germs may have adhering to them substances which cause the disease: as alumina, which takes up the coloring matter of a solution, and retains it so that usual processes will not deprive its particles of it, though it is not itself coloring matter. Charcoal and strychnia is another instance. In the same manner, bacteria might have adhering to them a substance which they would not give to any fluid, acid, or alkaline, except to the blood of animals.

Dr. H. Gradle, answering the above objections, remarked that alumina will not increase the quantity of coloring matter taken up. But as to the *germ theory*, its admirers based their opinions on the evidence of facts, while its opponents simply throw on it doubts which demonstrate nothing. Manipulating the parasites, cultivating them, and reproducing the disease, whose virulence is in exact proportion to the quantity of virus inoculated; killing the parasites, in raising the solution to a high temperature, and thus destroying the virulence of the inoculated fluid, these are positive facts which leave no doubts. We must admit that the virulence depends on something exactly corresponding to the size, number, and vitality of the bacteria. It is so in splenic fever. Then, in fowl cholera, the bacteria increase fast in the first two days, attain their maximum quantity at the fourth day, remain stationary for months, and then die. A want of food, not the accumulation of their secretions, checks their growth, as experiments demonstrated. A definite inoculation, a typical course, immunity from a subsequent attack, are also clear results.

Bacteria are not the disease, they are its cause. Disease is a condition of the body in which the play of organs can no longer adapt itself to the surrounding condition. It is produced, in cases under consideration, whenever the resistance to bacteria is no longer maintained. Bacteria may secrete a ferment or not. Urea may or may not depend on bacteria, since it can be produced also chemically. Yeast-cells are not essential to the alcoholic fermentation, for electric currents have produced it. "We do know that symptoms just like those of septicæmia have been produced by the injection of a chemical substance called septine." But in such cases of poisoning the course of the disease is neither regular nor typical. Pasteur finds that the inoculation of various substances causes symptoms resembling cholera. But the blood in those cases is not poisonous, and will not convey the disease. In anthrax, no symptoms arise before the *bacillus anthracis* has developed to some extent. At any rate, "no one has found any substance, except fungi, which will give rise to such symptoms when inoculated."

Dr. F. E. Waxham presented the greater portion of a small cambric needle which he removed from the arm of a patient, who could give no clue to its introduction, and did not remember having broken any needle in his hand nor arm.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 20, 1881, to February 26, 1881.

Meacham, Frank, Capt. and Asst. Surgeon. As soon as able to travel, to report in person at Department Headquarters, for assignment to a station. S. O. 32, Department of the East, February 19, 1881.

Gardiner, J. de B. W., Capt. and Asst. Surgeon. Granted leave of absence for one month, to take effect when relieved by a medical officer, with permission to apply for an extension of five months. S. O. 16, Department of Arizona, February 8, 1881.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 26, 1881.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

Feb. 26, 1881.	0	8	171	9	50	104	12	0

MEDICAL NIGHT SERVICE REPORT.—Dr. Ewing, executive officer of the Night Medical Service has reported to the Health Board yesterday that, during the month of January, 41 calls for medical assistance were responded to by 27 physicians of the service. Of these visits but one was paid for by the patient.

AMERICAN VETERINARY COLLEGE.—The sixth annual commencement of the American Veterinary College was held on February 24th, at Chickering Hall, before a large gathering of the friends of the college and of the veterinary profession. The prayer at the opening was made by the Rev. Dr. Newman. The conferring of degrees of D.V.S. to twenty graduates was made by the President of the Board of Trustees, Samuel Marsh, Esq. The valedictory address was delivered by David J. Dixon, D.V.S., of the graduating class, and the address to the graduates, by Jerome Buck, Esq., on the motto of the college *non nobis solum*.

The Trustees' prize of a gold medal was given to Robert H. Harrison, D.V.S., of Mossac, for the best general examination.

The Alumni prize, a set of standard works, was awarded to John Dougherty, D.V.S., for the second best general examination.

The New York State Veterinary Society prize, a gold medal, for the best practical examination, was given to John Dougherty, D.V.S., of New York.

Prof. Liautard's prize was given to James Ed. McNicol, of New York, for the best anatomical preparations; and John A. Leyton, of New York, obtained the silver medal for the best anatomical examination in the junior class.

THE SANITARY CONDITION OF NEW YORK CITY STABLES.—In the city of New York, the animals of all kinds, for labor and for food, foot up to the enormous total, in round numbers, of six millions and a quarter (6,250,000). For the year 1879, the New York Produce Exchange furnishes the following tabulated figures: Beeves, 567,837; cows, 7,336; calves, 156,227; sheep, 1,507,739; hogs, 1,725,537. While living, the manure and filth accumulated by them will not fall short of 50,000 tons; and, including the offal after being slaughtered, the accumulations must reach the total of not far from 75,000 tons of the fittest soil for the propagation of contagious diseases. At the same time, and added to these food-animals, New York houses and feeds 50,000 horses. The accumulations of manure and filth from these horses, in a year, amounts to 100,000 tons. For these 50,000 horses there are only 10,000 stables. Of these stables not more than one in a hundred is in perfect sanitary condition. About one-quarter of the horses are kept in dark, damp stables, or places equally bad. Of the two thousand cow-stables there are not ten which are in a sanitary respect perfect. Of the ten thousand horse-stables about three thousand have sewer-connections. The stables of the road-horses are much better than those of the truck, cart, and other work-horses. These latter occupy mostly damp, dark, illy-ventilated stalls, the plank floors being saturated with accumulations of urine and filth, which cause disease of the feet of the horse. —*Journal of Comparative Medicine and Surgery.*

CINCHONA CULTIVATION IN INDIA.—The reports upon this subject for the past year show that progress is continually being made. Cinchona cultivation in India, though its results as yet are by no means great, is at least an assured success. In 1879–80 there were produced 361,590 lbs. of dry bark, against 261,659 lbs. in 1878–79. Most of the bark is made up into an extract known as the "Cinchona febrifuge." This seems to act nearly as well as preparations of the pure alkaloids.

A new experiment has recently been made in the attempted cultivation of the Bogota barks.

SEX IN PHTHISIS.—Dr. T. S. Sozinsky has recently written an article (*Philadelphia Medical and Surgical Reporter*) upon the relation of sex to phthisis pulmonalis. According to the statistics given by him the disease is far more prevalent and fatal among females than among males, and this is especially the case between the ages of 10 and 15 years. According to the mortality statistics of the United States, during the year ending June 1, 1870, it appears that in Alabama 8 males between 15 and 20 years of age died of the disease, and 36 females; in Rhode Island, 14 males and 43 females; in Delaware, 4 males and 13 females; in Connecticut, 22 males and 50 females; and in Kentucky, 72 males and 170 females. Between the ages of 10 and 20 years it may be considered that twice as many females as males die of consumption. The proportion decreases with advanced age up to about 35 years; thus: at 25 about one-fourth more females die than males; at 30 about one-sixth more; and at 35 the number is about the same for the two sexes; beyond this age more males than females die from this cause. During the year ending June, 1870, there were 33,971 deaths of males and 35,925 of females from this disease in the United States. It is Dr. Sozinsky's opinion that the cause of the relatively large number of deaths among females early in life is not due to sex, but rather to unhygienic living. If the young of both sexes were similarly brought up he believes the difference would disappear in great part. Girls are not generally allowed to exercise as freely as boys, and they are too much confined within doors. The statistics given indicate that consumption of the lungs is largely due to other than hereditary causes; constitutional degeneracy, induced by improper modes of living, is the primal cause, and measures that will improve the general health will lessen the mortality from consumption of the lungs as well as from many other diseases.

PYÆMIC ORIGIN OF RHEUMATIC FEVER.—In discussing the question of the frequent occurrence (70 per cent. of cases) of throat affections with acute rheumatism, Mr. Wm. Stewart (*Lancet*) announces his belief that acute rheumatism is always caused by the absorption of pus. This absorption, generally, is of pus from tonsillitis, but it may come from an otorrhœa, a gonorrhœa, etc. Mr. Stewart proposes to publish a paper upon this subject.

Original Communications.

UPON THE SIGNIFICANCE OF FACIAL HAIRY GROWTHS AMONG INSANE WOMEN.

By ALLAN McLANE HAMILTON, M.D.

(Read before the New York State Medical Society, February 1, 1881.)

The significance of alteration in the growth of hair, and the condition of the skin and its appendages, have attracted the attention of many modern observers, and it has come to be generally acknowledged, I think, that such appearances have more than ordinary import as symptoms of nervous diseases. It is not uncommon, as we know, to find hair upon the faces of women, though, when discovered, it is not in any considerable quantity, and is the indication, as a rule, of a tendency toward masculinity or the arrival of that age when uterine and ovarian functions have ceased. It cannot be denied that when such growths take place in young women, in localities where hair does not usually grow, they are suggestive of some pathological process which may naturally be supposed to involve the sympathetic nervous system. Fabre* has quite lately drawn attention to the production of very striking hair-changes in consequence of various mental states in women, and other observers allude, at length, to the excessive growth of hair in paralyzed parts. Fabre refers to several instances. In one the patient was a mother who had suffered great mental anguish through the loss of a child. Another woman, who suffered from a uterine disease complicated by nervous symptoms, lost all her hair, but it returned as rapidly and grew vigorously under the use of appropriate treatment.

The appearance of hair, slight though it may be, is, I think, an inevitable result of an overactive and continuous exercise of functions of the uterus and ovaries, and is but part of the process which in the early stages of pregnancy is expressed by deposition of pigment in various places, by the bronzing of the skin, and the lively excitement of the organic nervous system. Kaposi† mentions the liability of women who have borne children to hairy facial growths, but believes that the appearance of hair upon the chin is found more often after the climacteric period than at any other time.

Enough is shown by the meagre literature of the subject to prove that there is a very close connection between the irregular or excessive performance of the functions of the female pelvic organs, and the phenomena of cutaneous malnutrition; and moreover that when their innervation is taxed, some peculiar exhibition of disordered vaso-motor function occurs in a remote part. My own experience leads me to divide the subjects of abnormal hairy growths into two groups:

1. Those in whom trophic cutaneous changes, such as acne, depositions of pigment, lesions of the nails, or hangnails, as well as slight hairy growths, occur in young women in connection with ovarian irritation, and with mental trouble or emotional disturbance evidenced by melancholia, and perverted moral sense; the altered sexual state being often connected with masturbation.

2. Those cases in which prolonged vaso-motor changes have existed, and in which uterine and ovarian function have disappeared.

In such cases the unlooked for development of hair may occasionally appear, and its site, time of growth, and character, may suggest its pathological character. Ollivier reports the case of a young woman of fair, soft skin, who, after an attack of typhoid, presented a curious appearance. The skin became rough, and a general growth of fine black hair took place all over the body. From time to time I have seen insane women who were the possessors of beards or growths of hair. Some of these cases, in fact most of them, presented some history of sexual trouble, and in nearly every instance the growth of hair was coincident with the development of mental diseases. In the beginning I was not prepared to attach much importance to the existence of beards or patches of hair upon the face, but lately I have been inclined to view the peculiar appearance and connection of this condition with others which I am convinced play as important a part, when they exist, as the condition of the hair of the insane mentioned by Bucknill and Tuke* and Darwin†. Godfrey‡ has observed the abnormal growth of hair upon the face of idiots and epileptics. A patient consulted him whose mother was insane; the patient had one sister in a lunatic asylum, "another nearly raving with neuralgia, and she herself epileptic. She was but thirty years of age, and grew a famous moustache and beard."

During one of my visits to the Hudson River State Hospital for the Insane I was shown a woman of middle age, upon whose chin an extraordinary growth of hair was visible—such growth having made its appearance since the development of her insanity. The subsequent discovery of other cases suggested to me that this condition of affairs might exist elsewhere, and I afterward made, with the kind assistance of Dr. Livingstone Hinckley of the resident staff, a careful search among the insane women at the Blackwell's Island Lunatic Asylum, and found many others. It will not be amiss to briefly allude to the history of several of these patients.

Case I.—Johanna G——, Westchester County, admitted to the Hudson River State Hospital for the insane, February 22, 1879; forty years of age; housekeeper; married; four children; good habits; common education; German. Patient was brought by the superintendent of the poor, who knew but little of her case. Was supposed by him to have been insane but two weeks. Said that she was the daughter of Christ. Neglected her family; prayed much and out of season; took food and slept irregularly, but was quiet and easily managed. General strength fair.

February 23d.—Wanders through the ward, whispering in German; was noisy last night; ordered chloral, ʒ ss., tr. hyoscy., ℥ ij., nightly. No special change till the morning of March 3d, when she became suddenly very destructive, tore up in the course of fifteen minutes eight pillows, then became as before, not noisy, but talked continually in a low voice to herself.

April 16th.—Refuses all medicine. Sleeps but little at night, but is not noisy.

May 2d.—At times is noisy. Stoops down to the floor and converses with imaginary persons, spirits, etc. *Quite a beard has grown on chin since her admission:* had a few short hairs then, but these have very

‡ Diseases of the Hair, p. 31.

greatly increased in numbers and length. Says she has had hair on her face during the past four years, but not previous to this. Menstruates regularly. No special change has occurred in her mental or physical condition for many months, or, indeed, since admission. Occasionally will be noisy. Talks to and gesticulates at imaginary persons almost continually. Resists all treatment.

The above notes were taken by Dr. C. H. Langdon, who assisted me materially in my examination.

Mrs. G. is a spare woman of medium height, of decidedly disagreeable personal appearance, much of which is due to a long moustache and two or three peculiar tufts of wiry black hair which droop from the chin. There are tufts of considerable thickness on the left side, which I have seen upon two occasions, and find to have grown more than half an inch in three months. The skin is the seat of discoloration. There are "bronze spots" on left temple and chest. Both sides contain spots of pigment, the left, however, more than the right. There is no difference in the size of the mammary or other glands, but the left nipple is, if anything, more prominent than the right. The left side is cooler than the right. Dr. Langdon took a number of surface-temperature observations, and the average is as follows:

	Right side.	Left side.
Face	99°	98°
Ovary	99°	100°
Palm of hand	99°	90°

The right axillary temperature was 98⅛°, the left 98⅝°. The nails of both hands, but especially left, were crenated and irregular in growth, and there were hang-nails. There was, if anything, a slight increase of size of the left side, the various circumferential measurements giving a difference of from one-half to one inch in favor of the left side. Uterine examination revealed a very small uterus. The growth of hair upon the pubes was normal, but slightly thicker on the *right* side. The new growth of hair is wiry, black, and extremely dense in places. Heart-sounds normal.

Case II.—Nancy S——, *dementia*, colored, forty-five years of age, chronic mania. Admitted to the Hudson River State Hospital for the Insane, December 8, 1877. Has had no children. She has not menstruated since admission (present date, August, 1880). The patient has irregular tufts of hair upon her chin and just anterior to ears, upon both sides (see cut). She has a slight moustache. The hair is longer upon the right side, and it is of active growth and quite wiry and black. The temperature of the left side of the body is lower than the right. Her hair-growth began with her insanity. She is often violent and destructive, and will not permit physical examination.

Case III.—Sarah H——, forty-five years of age. Admitted to the Hudson River State Hospital for the Insane, September 23, 1879. Prostitute. Syphilitic insanity, followed by dementia, duration two years. Patient has goitre of recent growth, which is larger on right side than on left. Marked tufts of hair upon upper lip, chin, and sides of face. The growth is of comparatively recent date, and is about one and one-half inch long. Lowered temperature on left side. Has bronzed spots upon body, and general mottling. There is no heart trouble. She has not menstruated since her admission.

Case IV.—Sarah Ann S——, admitted to the Hudson River State Hospital for the Insane, February 16, 1878. Aged thirty-two years. Mother's mother insane; insane three years; acute mania, followed by dementia. Has had two children. Separated from husband. This patient has abundant beard and moustache of light color, which appeared with commencement of insanity, and since has grown to a considerable length, the beard being nearly two inches in length. She has menstruated regularly. The growth is

very marked on the left side. The eyebrow of the same side is much heavier and the eyelashes are perceptibly larger. The left iris contains spots of pigment, which are absent on the other side. The surface temperature is lower on the left side. The nails are crenated and horny. Small anginoma are found scattered over the left side of the body, and these are about the size of a large pin-head and confined to the upper part of the trunk. There is slight thyroid enlargement, but no heart-murmur. The left breast seems larger than the right.

At Blackwell's Island my search was attended with great difficulties, because so little was known of the patient's age or antecedents, but with the assistance of Dr. Hinckley I found several women who presented appearances resembling in every respect those already mentioned. Most of these cases were well advanced in life, and the hairy growth had not the significance it would have had in younger women; still the excessive length of the beard of these women, the luxuriance of the hair and its preponderance upon one side, gave it a different appearance from that usually found in old women. In two of these cases the beard began at an early age, and was quite dense. An unmarried woman was thirty-nine years old, and her insanity began twenty-four years before, in melancholia, which developed into mania, and she subsequently became demented. The hairy growth began ten years ago, and is quite dense and longer on the right side. It has changed color within the past two or three years, the original color having

been brown. It now contains tufts of gray. There are many moles scattered on body, but particularly on right side, and some bronzing. A second case, thirty-seven years old when seen. Her trouble began ten years ago as mania followed by dementia. She was also unmarried. She possesses a moustache most abundant upon the left side, and a collection of stiff, long, black hairs upon the chin.

Of four other women in whom the diagnosis of dementia was made, the beard was longer and more dense on the right side in three, in the other it preponderated on the left side. In one case the growth was white, with sharply defined patches of black. In another case there was a small displaced uterus. In two others there was dysmenorrhœa. In all there were spots of skin-discoloration and angioma; the hair of the head was abundant and coarse; the temperature was lowest upon the side where the hair was most developed.

Arnozan* refers to the rapid development of hair as a result of various nerve-lesions, and says traumatic neuritis is most apt to be followed by hairy growths, which disappear when the neuritis is cured. As a very rare accompaniment of paralysis it is occasionally the case that a dense growth of hair makes its appearance in paralyzed parts. Such a case is detailed by Jelly,† the patient being a young Spaniard, eighteen years of age, who, after a fall, suffered from complete paralysis commencing at the last dorsal vertebra. Coincident with the paraplegia his body below the point of injury became the seat of a hairy growth, which extended about the nates and down the legs to the ankles. In some places it grew to such a length that it could be readily curled. I have seen cases of paralysis in which the hairy growth occurred in places which were the seat of trophic paralysis, and cases of infantile paralysis in which the limbs were covered by an active growth of new hair have been observed. Buchner,‡ in speaking of baldness of nervous origin, refers to the trigeminal and occipital nerves as those involved in cases of abnormal hair change, and Virchow is disposed to assign the pathological seat of facial hairy growths to the trigeminus, a conclusion he came to after his investigation of the celebrated Ava cases, in which two men and a woman were the subjects, the dense and peculiar growth of hair being confined to the face and neck.

From the foregoing, and from a consideration of the well-established fact that mental shock and the influence of powerful emotions are productive of trophic degeneration and loss of hair, it may be assumed that diminution of innervation is apt to be followed by trophic alteration, evinced either by the loss or increase of hair; that disorders of the fifth nerve are connected with such changes, and that the condition is one of a neuropathological character there can be little doubt. This is still further borne out by the circumstance that in cases of migraine connected with cerebral functional alteration, the trigeminal neuralgia not unfrequently results in external vaso-motor changes of the most varying description.

Of course the remote pathology must be considered from a purely theoretical and consequently unsatisfactory standpoint. It would appear that the normal balance between the cerebro-spinal filaments and those belonging to the sympathetic system concerned in the control of vessels engaged in nutrition, was lost in such cases, and that the energy before expended in the innervation of the pelvic organs was directed in a new channel. Dr. Emmet, in his work upon diseases of women, makes the statement that those women in whom normal uterine innervation is not exercised, are usually those who suffer from new growth of various kinds. The same reasoning might apply in the case of peripheral disorder such as that which forms the subject of the paper I have just read.

A consideration of the cases to which I have alluded, I think, will show that:

First.—Abnormal growth of hair, especially upon the face, is frequently closely connected with disturbed function of the pelvic organs of women.

Second.—That in the insanity of women, especially when it lapses into dementia, and cutaneous nutritive changes exist, such growths of hair are by no means of uncommon appearance.

Third.—That their unilateral character, so far as preponderance in growth is concerned, and their association with unilateral cutaneous lesions, such as bronzing and nail-changes, indicate their nervous origin.

Fourth.—Their appearance chiefly upon the face in insane patients, and relation to trophic disorders incident to facial neuralgia, points to the fifth nerve as that concerned in the pathological process.

Fifth.—The development of hair, with the deposit of pigment and skin lesions, and occasional goitrous swellings suggests the inference that the neuropathological process which leads to the growth of hair in the chronic insane, is akin to that which gives rise to Addison's disease.

As I have said, there are many cases which do not impress us because they include women of advanced age. These I exclude altogether, but I shall be satisfied if I succeed in convincing my hearers that when any considerable growth of hair occurs upon the face of female insane patients, it is indicative of an unfavorable form of insanity, and such especially is the case in those women who have not reached middle age.

Veterinary Education in England cannot be in such a vastly superior condition to that in this city, if we may judge by the following quotation from an editorial in the *Veterinary Review*. The editor says: "We cannot be accused of exaggeration when we venture to assert that scores of young men, very imperfectly educated—scarcely able to read and write their own language—who may have failed in other pursuits, and are without any idea of the requirements of a veterinary surgeon, have entered our schools, and in due time received their diploma without ever having given a dose of medicine, performed the slightest operation, or gained the slightest insight into the ordinary routine practice."

There is a very active discussion going on in the same journal, as to whether the English veterinary students keep themselves as clean as they ought. This important matter has not yet been decided.

Such comment and discussion as the above cannot occur in the colleges of this city, at least. We should add, perhaps, that the Royal College of Veterinary Surgeons has recently resolved that no student shall receive a diploma without having had a year's pupilage.—*Journal of Comparative Medicine and Surgery.*

CHLORAL HYDRATE.

By H. H. KANE, M.D.,

NEW YORK.

Part III.

THE DOSE—POISONING BY AND ITS TREATMENT.

It is interesting to note how rapidly the dose of chloral has diminished from those tremendous ones so commonly employed when the drug first came into notice. Liebreich[1] gives as the proper dose for new-born infants 0.04 gramme ($\frac{2}{3}$ grain) and 0.09 gramme ($1\frac{1}{2}$ grain) for children above one year of age. Bouchut[1] and Giraldès[1] have prescribed one gramme at four years, and three to four grammes at from five to fifteen years. Labbée[2] says that the dose for an adult should not be above five or six grammes (75 to 90 grains) although as high as ten grammes (150 grains) have been given without accident. At its first introduction, chloral was given regularly in from four to ten-gramme doses, especially in France and Germany. Sixty grains were given as a dose in England and America, but from twenty to thirty grain doses were most commonly employed. From the literature of the subject, and from the letters of my correspondents, I find that the average dose is about ten grains, occasionally fifteen or twenty, and less often thirty and forty grains. Professional opinion has greatly changed in the past seven or eight years, and to-day the feeling of distrust, owing to the large number of recorded cases of poisoning and death from this drug, keeps the dose within reasonable limits. As a rule, one third of a grain may be given to a new-born child, one grain to a child one year old, two or three grains to a three-year-old child, five grains to a child from five to ten years of age, from five to eight grains to youths from ten to sixteen, and after that from ten to thirty grains, as the case may require. Children bear larger proportional doses of chloral than adults.

Certain severe spasmodic affections, as tetanus, puerperal and infantile convulsions, etc., require larger proportional doses, and they must be often repeated in order to get the desired effect.

The question as to whether it is better to give small doses frequently repeated, or a single large dose, has created considerable discussion. In insomnia, and indeed in the majority of diseases, functional and organic, I find it to be the opinion of the best men in the profession that a single good impression is preferable to saturation with small amounts, the latter being more liable to give rise to the evils of cumulative action.

Surprisingly large amounts of chloral have been taken in the course of twenty-four hours, oftentimes without any appreciable ill effect. Dr. James J. Healey,[3] of Newburyport, Mass., reports the case of a man, forty years of age, who, while suffering from the effects of a two weeks' debauch, took, in the course of ten hours, six hundred grains of chloral, "with the effect only of producing five or six hours of restless sleep."

Dr. P. C. Williams[4] relates a case where a similar amount was believed to have been taken, and where the patient recovered without any treatment. The case of a very sleepless man (mentioned in the *Lancet*) is not so extraordinary. Failing to procure sleep from smaller doses, he took, in all, four hundred and twenty grains. The only inconvenience was a temporary loss of power in the legs.

Dr. Ballantyne[5] of Dalkeith, gave 1,440 grains in twenty-four hours, in a case of tetanus. The patient recovered.

The case of a child twelve and one-half years old is recorded,[6] where, to quiet tetanus spasms, two hundred grains of chloral was given daily.

The following are some of the largest amounts given in twenty-four hours by my correspondents: H. G. Dearborn, Nashua, N. H., 240 grains; J. H. Arton, Hamilton, Bermuda, 240 grains; J. D. McCleary, Indianola, Iowa, 240 grains; C. A. Bryce, Richmond, Va., 480 grains; O. D. Abbott, Manchester, N. H., 100 grains; E. Y. Chilton, Albany, Ky., 180 grains; C. H. Greenough, New York City, 480 grains in five hours; T. C. Tipton, Williamsport, Ohio, 180 grains; Wm. B. Davis, Grapevine, Texas, 600 grains; E. N. Tull, Fairland, Ind., 180 grains in nine hours; Virgil O. Hawdon, Providence, R. I., 160 grains; E. H. Coover, Harrisburg, Pa., 480 grains; E. P. Easley, New Albany, Indiana, 180 grains; Norton Folsom, Boston, Mass., 240 grains; A. P. Hayne, San Francisco, Cal., 200 grains, N. C. Husted, Tarrytown, N. Y., 240 grains; J. Foster Burt, Boston, Mass., 480 grains; R. W. Bruce Smith, St. Thomas, Ontario, 250 grains; C. L. Wilson, Atlanta, Ga., 160 grains; A. Atkinson, Baltimore, Md., 120 grains; E. A. Cobleigh, Athens, Tenn., 496 grains, etc.

Dr. F. L. Forsyth, of Providence, R. I., gave ʒ j., q. 2 hor., in a case of tetanus. In none of these cases did death result from the use of such large amounts.

Having seen how much may be taken without producing symptoms of poisoning or jeopardizing life, it will be of interest to study a few of the many cases of poisoning from both small and large doses.

Laboulbène[7] gave fifteen grammes a day to a girl seventeen years of age, and cured chorea. Mr. Worms, of the Hospital Rothschild, gave twenty grammes a day, for a week, without any appreciable bad effects. Patient, a female, seventeen years of age, hysterical.

The subject of poisoning by chloral hydrate has already received full and careful study at the hands of competent observers in England, France, and Germany. Richardson[8] was one of the first to study the matter in detail.

There are really two conditions that result from a poisonous dose of this drug: one in which coma is prominent, anæsthesia marked, with slow pulse and slow respiration; the other where the drug seems to have suddenly and forcibly thrown itself upon the heart and paralyzed it. The former are by far the most frequent, and the difference in the action of the drug seems to be due to some peculiarity of the individual, possibly an inherited or acquired tendency to death by the heart.[9] It cannot be accounted for, I think, on the score of impurities in the drug.

Let us suppose a patient to have taken an overdose of chloral hydrate on an empty stomach. The first symptom will be sleepiness, soon growing so intense as to render the individual no longer able to hold the eyelids open. He sinks into a quiet sleep that momentarily becomes more profound. Stertor gradually develops, the face becomes faintly flushed, then of a deep red color, possibly mottled with

blotches and streaks of purple. The pupils, at first normal, gradually contract, momentarily dilating if the individual is disturbed. Respiration becomes more labored. The pulse rises to 100 or 120, full, but feeble; the eyes become bloodshot, the lips dry, parched, and swollen; the temperature is found to have fallen from one to five degrees. The respiration may now grow slower and more stertorous, occasionally intermitting, or it will increase in frequency, becoming rapid and shallow. The hands and feet will be found cold, and sometimes covered with a clammy sweat. Anæsthesia is marked everywhere. The cornea may be touched with impunity—the conjunctivæ have lost their sensitiveness. Pinching and pricking the skin, tickling the soles of the feet, the application of a strong electrical current, elicit little or no response. The individual usually remains in this condition for hours; then, if it is to be death, circulation and respiration gradually or suddenly fail, and the chloral sleep eventuates in the sleep of death. If it is to be recovery, the temperature gradually improves, the pulse increases in force, the respiration becomes less labored; signs of returning consciousness, slight but positive, show themselves. He moves the hand and possibly a leg, the pupil commences to dilate, the dark color of the face clears somewhat, and gradually, step by step, he traces his way back to the condition existing before the drug was taken. For days afterward he may feel sleepy and stupid, the eyes may smart, the throat feel dry, and there may be a paralytic condition of some part or organ, as the leg, arm, bladder, pharynx, or rectum.

Cases of poisoning where the symptoms have followed about this course may be found as follows: B. W. Richardson,[10] 240 grains, in three doses; breathing 28 and regular; *pupils dilated*; pulse 64, soft, full, and steady; occasional intermission of heart-sounds; recovery. Dr. James Rodman,[11] of Hopkinsville, Ky., 270 grains; pupils contracted; recovery. Dr. J. E. Halbert,[12] over 400 grains; *pupils irregular*; later slightly contracted; recovered. Dr. A. G. Craig,[13] 80 grains, in divided doses, during labor; pulse 150, small and weak, respirations 10 and stertorous; pupils slightly contracted; death on second day from exhaustion, child having been born in the meantime. ——,[14] 180 grains; recovery. Dr. Stone,[15] at St. Thomas's Hospital, 150 grains; pulse 108, feeble; temperature 98.6° F.; respirations 42; pupils contracted; recovery. Dr. P. E. Bishop,[16] 165 grains; recovery. Dr. Francis F. Brown,[17] 80 grains; sudden collapse after an hour; pupils contracted; recovery. Dr. Edmund White,[18] 190 grains; recovery. Mr. Hulke,[19] 320 grains; recovery. ——,[20] 460 grains, recovery. Dr. R. J. McKay, 300 grains; several clonic spasms; pupils contracted, but would at times dilate. Chouppe,[21] quantity unknown; temperature 30.2° C.; pupils contracted; recovery. Dr. D. Young,[22] 180 grains; recovery. ——,[23] 200 grains; recovery. Dr. Manjot,[24] 186 grains; recovery. Levenstein,[25] 360 grains; recovery. In one of these cases clonic spasms showed themselves, a very unusual thing in man, but not so in certain animals. The following correspondents have sent me histories of poisoning by chloral: M. L. Holbrook, New York, 200 grains; Roswell Park, Chicago, Ill.; James Donaldson, London, Eng., 60 grains; A. P. Hayne, San Francisco, Cal., 60 grains; A. Atkinson, Baltimore, Md., 160 grains. H. Hunt, Beloit, Wis., 240 grains; F. D. Lente, New York City, 15 grains, prolonged sleep; A. R. Kilpatrick, Navasota, Texas (in practice of another physician), 240 grains; F. L. Forsyth, Providence, R. I., 150 grains; George B. Twitchell, Keene, N. H., 180 grains, pulse slow, respiration slow; W. P. Bolles, Dorchester, Mass., 8 grains to infant eight months old, temperature 103°, pupils contracted when still, dilated when moving; A. Ady, West Liberty, Iowa, 180 grains.

In the case related by Dr. Bolles, the high temperature, 103°, is very unusual, it being generally below normal.

The question has often been asked, "What is the smallest amount of chloral known to have produced decided symptoms of poisoning?" The following, from a letter from Dr. W. R. Upham, of Yonkers, is interesting in this connection: A woman, thirty-four years of age, of nervous temperament, and at times hysterical, was given ten grains of chloral hydrate to procure sleep. She soon became profoundly comatose, with congested eyeballs and contracted pupils. There was slight twitching of the arms and legs. She fully recovered after some hours under appropriate treatment.

Information of the largest amount from which a patient has recovered, is sent me by Dr. Charles Warrington Earle, Professor of Diseases of Children in the Women's Medical College of Chicago: "A young man, about twenty-eight years of age, a *triple* inebriate (alcohol, opium, and chloral), took at once fifteen grains of morphia, and one-half of a mixture containing

600 grains chloral hydrate,
240 grains potass. bromid.

In twenty minutes he took the remainder. He was in a very critical condition for hours, and was only saved by the administration of stimulants, strychnia, and electricity."

Dr. Paul Kretschmar, of Brooklyn, writes me of the case of a woman who recovered after taking 420 grains.

Dr. O. A. Gorton, of New York City (letter), saw a nearly fatal result from about seventy grains; temperature normal; pupils sometimes dilated, sometimes contracted.

I shall now give a few of those cases where the heart seems to have been rapidly overwhelmed, and in consequence the symptoms were somewhat modified.

Dr. Minot[26] relates the case of a lady forty-five years of age, who was given forty-five grains of chloral. This was followed by deep sleep. On awaking, fifteen grains more were given, when profound collapse occurred.

The case of a man thirty-four years of age, suffering from an attack of delirium tremens, is related by Dr. Frantz,[27] where no sleep following one and one-fourth gramme of chloral on one night, the same

dose was given the next night. He slept all night, but awaking was followed by profound collapse, in which he died. Also a case of like nature, where death followed two doses of thirty grains. The man slept all night, but died in collapse in the morning. An autopsy was made in each case, but nothing was found sufficient to account for death, and therefore Frantz believes that it was due to the chloral.

Dr. J. R. Reynolds[28] relates the following peculiar case. The chloral hydrate seems to have affected the vessels without affecting the heart in like manner. A middle-aged lady, who was in the habit of taking chloral for the relief of neuralgia, gradually increased the dose, until one day she took forty-five or fifty grains. There was complete relief to pain, but in an hour "faintness" appeared, and soon became alarming. Cold extremities, sinking at pit of stomach, dyspnœa, and confusion of thought. Pulse weak, irregular, and intermittent, *but heart at same time acting regularly*, with increased frequency and diminished force. On stimulants she rallied and seemed doing well. In another hour the same condition of collapse suddenly showed itself. Dyspnœa and sense of suffocation marked. She fully recovered on stimulants.

"Attacks of pallor with great præcordial pain in few minutes after taking chloral. Morning headaches follow doses of even ten grains in the neurasthenic." —*Geo. M. Beard.*

"Occasionally seen great depression, feeble and slow pulse, with sinking tendency. Promptly relieved by alcohol, ammonia, or nux vomica."—*J. H. Nordlin*, Rome, Ga.

"One patient, a female, cannot take it without becoming very faint. Cannot explain it."—*J. W. Parsons*, Portsmouth, N. H.

In the *Lancet* appears the case of a man of middle age, with a boil on the buttock. It was lanced, and at bedtime he took nine grains of chloral. Shortly after he became "stone-cold," his teeth were fixed, and he stared about wildly. Cold perspiration wetting pillows and sheets. Warmth, and brandy and water revived him. The next morning he was pale and anxious.[29]

In a case of hysteria and dysmenorrhœa, Dr. Paddock[30] produced profound collapse, with four fifteen-grain doses of Schering's chloral. Chloral had been well borne the previous night. The patient was well stimulated and recovered.

Dr. H. W. Fuller,[31] in an article entitled "Dangerous and Fatal Results from the Use of Hydrate of Chloral," relates the case of a man suffering with slight anasarca and bronchitis due to Bright's disease. Thirty grains chloral produced burning in chest, then violent delirium, followed by almost fatal collapse. He recovered. Thinking this might be due to rapid conversion into chloroform from excessive alkalinity of the stomach, he repeated the dose again in a strong acid solution, but with the same results.

The following peculiar case of this type is sent me by Dr. T. B. Camden, of the West Virginia Hospital for the Insane, Weston, W. Va.: "A lady in the hospital has taken chloral twice. At each time she became cold, had a peculiar dead or numb feeling, with great oppression about the heart, and unconsciousness; believe a large dose would be fatal to her. She was relieved in both instances by emetics and stimulants."

[28] Practitioner, 1870, p. 189.
[29] New York Medical Journal, 1872, p. 332.
[30] Boston Medical and Surgical Journal, August 11, 1870.
[31] Lancet, June, 1871.

Dr. G. G. Davis, of Frewsburg, N. Y., produced alarming symptoms in a typhoid fever patient in a very short time by a single dose of ten grains. Liebreich has cautioned against its use in this affection, but others have used it with success to quiet restlessness and reduce temperature. A case of sudden collapse is also given by Dr. Brown.[32]

In still another class of cases, a large dose of chloral simply throws the patient into a profound sleep,[33] lasting sometimes for days. After awaking there are seldom any bad symptoms beyond the fact that the sleepiness sometimes continues to be felt for some days.

In still another class the drug produces no sleep whatever, the patient remaining in a stupid state, but not sleeping. Occasionally delirium, vascular excitement and hallucinations are produced.[34]

In considering the cases of death caused by morphia when used subcutaneously, I took occasion to suggest that there might possibly be great danger in giving morphine after having given chloral or bromide of potassium in large doses.[35] Since then I have received the history of two cases, one from Dr. Roswell Park, of Chicago, and the other from Dr. A. Ady, of West Liberty, Iowa, that lend weight to this view, as also do the following:

G. P.[36] reports the case of a man aged thirty-five years, suffering from delirium tremens; no sleep for a week. Was given one hundred and twenty grains of chloral in twelve hours, then one grain hydrochlorate of morphia in two hours. Sleep followed. Then one-half grain morphia in course of a few hours. Snoring at 8 A.M. Dead at 9 A.M.

A homœopathic doctor of Canada was killed by another of the same school.[37] He had fissure of the anus. Operation under chloroform; then forty grains of chloral hydrate, soon repeated; then one-fourth grain morphia. Death in one-half hour.

Prof. N. R. Smith records[38] a case of death from an unknown amount of chloral and the subcutaneous injection of one-quarter grain of morphia for neuralgia. Prolonged sleep resulting in death.

T. S. Shields, M.D., of Crawfordville, Ga., reports (*Southern Medical Record*) the case of a woman who had been taking daily forty to sixty grains of chloral before she came under his care, and who subsequently became habituated to the use of opium. She was subject to attacks of hysteria, against which the commonly used remedies were employed. In an attack characterized by active delirium, wakefulness, with a pulse of 120, respirations 24, and no fever, ten grains of chloral in water were administered. An hour or two before, the patient had taken six grains of gum opium. A quarter of an hour after the chloral was taken, symptoms of opium-poisoning supervened, and in a very short period progressed to complete arrest of respiratory movements. After great efforts respiration was restored by means of caffein, atropia, and galvanism. Since the patient had been accustomed to the use of opium, the writer attributes

to the chloral the intense effect produced in this instance.[39]

Dr. H. W. Boyd, of Chicago, writes: "I also used it in a case of tetanus from gunshot-wound of the knee-joint. The spasms were severe and I had used a great deal of morphine hypodermically, and had also kept him under ether and chloroform for many hours at a time. Finally I gave him an injection of between thirty and forty grains per rectum; in twenty minutes he went to sleep with loud, distressing snoring. His temperature went down, his pulse failed, and after ten hours of snoring he awoke perfectly conscious, talked perfectly rational for thirty or forty minutes, and then sank back and in three hours more died. Now, what killed that man? I was ever so careful with my morphine injections; quit them several hours before I gave the chloral. The chloral certainly stopped the spasms. But do you think the forty grains chloral, given after the morphine and inhalation of chloroform and ether, caused that death? He had no spasms when he died."

Dr. A. R. Kilpatrick, of Navasota, Texas, writes me as follows: "Two or three cases of the following character have occurred here in the practice of one of the physicians. One is a stout Northern (Connecticut) lady, fair complexion, blue eyes, good general health, and no organic disease, mother of two or three children, and then about thirty-four years old. I do not recollect what her ailment at the time was, but think it was catarrhal fever, and the doctor gave chloral to procure sleep, as she failed to rest well, and that seemed to be what she needed most He gave chloral in preference to opiates, to avoid constipation. After waiting, himself in the house, a sufficient length of time for the morphine to exert its influence and it failing to produce sleep, he gave her about ten grains of chloral in camphor-water, and, I believe, either syrup or sugar. In fifteen minutes or less time she ceased to breathe and presented signs of complete syncope, and the usual remedies for restoration were promptly resorted to and she was relieved. One or two other similar cases have occurred in his hands, where chloral was used *consecutively* with opiates. It seems immaterial whether the chloral is used first or last—these unfavorable effects follow; but, if chloral is given at the same time *with* the morphine or opiate, no bad symptoms arise. I have used both together with the happiest results, nor have I observed any phenomenal or abnormal consequences from using them consecutively; but since I heard of these cases I am particular not to run a risk."

The danger is sufficient to justify care in the use of one drug in full doses, after full doses of the other. In Dr. Ady's case, one sixth grain of morphia was injected subcutaneously after twenty drops of a saturated solution of chloral hydrate had been given. Complete anæsthesia, deep sleep, etc., ensued, and life was despaired of. She was finally restored by means of atropia and whiskey hypodermically, and whiskey by the rectum. In Dr. Park's case the amount of chloral was small, that of morphine large. Both were given subcutaneously.

At 11.45 he was summoned, to find her gasping for breath, face and lips livid, pupils contracted, pulse about 100, perspiration profuse, extremities warm, temperature, 99½°, respirations 3 to the minute, comatose. Injections of atropia and brandy, electricity, and artificial respiration, finally restored her.

The pupils are, in the majority of cases, contracted, occasionally irregular,[40] and rarely dilated. Richardson and Cleveland claim that the pupil is usually dilated, as also Coghill,[41] who quotes them. He seems to think that contraction of the pupils occurs where the action of the drug is rapid and chiefly on the lungs, while when action is slower and chiefly on the heart the pupils are dilated. He bases his treatment on this distinction, using amyl in the first case, strychnia in the second. This theory is, however, entirely disproved by the letter of Dr. William Sedgewick,[42] which reads as follows:

"SIR—In a case of poisoning by chloral hydrate, recorded in your journal, June 28, 1879, it was noted that the pupils were 'strongly contracted to the size of a pin's head,' and Dr. Coghill, in his report of the case, after referring to the observations of myself and others on this subject, has suggested that any apparent discrepancy in the condition of the pupils 'must be sought for in the difference of the amount of the drug swallowed, and the corresponding rapidity of its action.' But clinical observation has shown that dilatation of the pupil occurs only as a very rare and as an exceptional condition during the hypnotism produced by this drug. In some 'Clinical Notes on Poisoning by Chloral Hydrate,' which I read before the Harveian Society, in October, 1878, I gave a careful analysis of the recorded cases of poisoning by chloral hydrate, and I pointed out that contraction of the pupils had been almost invariably observed during the hypnotism produced by it. Among the observations in this paper are a well-marked case of recovery from 240 grains of chloral hydrate, observed by myself (*Lancet*, August 3, 1878), in which there was extreme contraction of the pupils; Dr. Levinstein's case of recovery from 300 to 360 grains of the drug, in which, six hours after the poison had been swallowed, there was 'extremest contraction' of the pupils (*Medical Times and Gazette*, September 9, 1876); and a corresponding non-fatal case, recorded by the same observer, in which 360 grains of chloral hydrate had been swallowed in one dose, and in which it was noted, one hour and a half afterward, that the pupils were contracted (*Lancet*, February 21, 1874); a non-fatal case observed by Dr. David Young, of Florence, in which 180 grains of chloral hydrate had been swallowed in one dose, and in which it was noted, three hours afterward, that the pupils were firmly contracted, whilst, six hours later on, it was again noted that the pupils were contracted (*British Medical Journal*, December 25, 1875); a non-fatal case observed by Dr. G. W. Cole, in which an elderly man had swallowed 240 grains of chloral hydrate in one dose, and in which it was noted, three hours afterward, that the pupils were 'strongly contracted' (*Lancet*, November 11, 1876); a non-fatal case, observed by Mr. Hulke, in which 320 grains of chloral hydrate were swallowed in one dose, and in which it was noted, very soon afterward, that the pupils were extremely contracted (Clinical Society, November 27, 1874); a non-fatal case, observed by Mr. Snell, in which apparently more than 480 grains of chloral hydrate had been taken in one dose, and in which, almost immediately after the poison had been swallowed, it was noted that the pupils were 'much contracted' (*British Medical Journal*, March 27, 1875); and a non-fatal case, observed by Dr. Tizard, in which 160 grains of chloral hydrate had been taken

[42] Ibid., September 20, 1879.

in one dose, and in which it had been noticed, soon afterward, that the pupils were 'moderately contracted' (*British Medical Journal*, September 21, 1878). A fatal case has been recorded by Mr. Thomas Chambers, in a lady, aged seventy years, who died in about nine hours and a half after taking only ten grains of chloral hydrate, and in which the pupils were observed to be 'slightly contracted' about fifteen minutes after death had apparently occurred (*British Medical Journal*, May 25, 1872). Among the more pronounced symptoms of poisoning by chloral hydrate, referred to by Dr. Erlenmeyer (*Med.-Chir. Rundschau*, October, 1872), and by many later writers on the subject, is contraction of the pupils: and Dr. McKendrick, in a paper on the 'Physiological Action of Chloral and Bromal Hydrates and Iodoform' (*Edinburgh Medical Journal*, vol. xx., 1874–75), has demonstrated that the pupil contracts with great rapidity to its smallest diameter after the administration of bromal hydrate in rapidly poisonous doses.

"This more or less strongly marked contraction of the pupils in poisoning by chloral hydrate (which is antagonistic to the local action of atropine on the iris) appears to be simply an exaggeration of their condition during the hypnotism produced by the drug when given in medicinal doses; and M. Labbée, in his article on Chloral (*Dict. encycl. des sciences méd.*, tome 16), states that there is contraction of the pupils after twenty to sixty grains of the drug have been administered either by the mouth or by the rectum. Previous to the occurrence of hypnotism, I have observed, in common with others, that there is a tendency in the pupils to dilate. According to the observations of Dr. Hammond (*New York Medical Journal*, February, 1870, quoted by M. Labbée), this preliminary dilatation of the pupil is associated with decided vascularity of the inner structures of the eye; but when, soon afterward, sleep has occurred, this hyperæmia is succeeded by an exsanguine condition of the retina and contraction of the pupil. I have, moreover, had the opportunity of observing, in common also with others, that when, by galvanism or by any other means, a chloralized patient has been temporarily roused from sleep, the contracted pupils at once dilate; and Van Lair has remarked that the contraction of the pupils, during the hypnotism produced by chloral hydrate in non-poisonous doses, can be overcome, and that the pupils can be made to dilate by irritating strongly the skin, or, better still, by uttering a loud cry close to the ear of the sleeper. On the other hand, Dr. B. W. Richardson (*British and Foreign Med.-Chir. Review*, January, 1875) has recorded the case of a middle-aged man who had dilatation of the pupils some hours after taking 240 grains of the drug in divided doses; and Dr. Cleveland lately stated, at a meeting of the Harveian Society, that dilatation of the pupils occurred in an otherwise exceptional case of poisoning by chloral hydrate, under his own observation.

"With reference, therefore, to the condition of the pupils in cases of poisoning by chloral hydrate, it must be admitted that contraction is the rule, and that dilatation is an altogether exceptional phenomenon during the hypnotism produced by this drug in the human subject. MM. Feltz and Ritter have observed dilatation of the pupils after the injection of chloral hydrate in poisonous and rapidly fatal doses into the veins of a dog. But the value of the clinical evidence adduced seems to be in no degree lessened or impaired by experimental observations on the effects produced by this or by other narcotics on any of the lower animals; and it is, moreover, well known that the effects produced by opium in causing contraction, and by belladonna in causing dilatation of the pupils in the human subject, are not in accordance with experimental observations on such of the lower animals as are physiologically capable of resisting the usually poisonous influence of these drugs.

"Yours, etc.,

"WILLIAM SEDGWICK.

(To be continued.)

TRUE CYST OF THE VOCAL CORD.

PARTIAL APHONIA—SPONTANEOUS RUPTURE—CURE—WITH REMARKS.

BY GEORGE M. LEFFERTS, M.D.,

CLINICAL PROFESSOR OF LARYNGOSCOPY AND DISEASES OF THE THROAT, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING LARYNGOSCOPIC SURGEON TO ST. LUKE'S HOSPITAL, ETC.

THE following case, aside from its rarity, is, I think, of diagnostic interest as suggesting the possibility, not to say probability, that others of similar character may, in default of a laryngoscopic examination, be readily mistaken for cases of so-called hysterical aphonia, and for the following reasons: the main and striking symptom in each affection is, without apparent cause, sudden loss and ultimately as sudden recovery of the voice. No other local symptoms of import present themselves aside from this one, and either affection may occur unexpectedly, in an otherwise to all appearances perfectly healthy individual; moreover, in the recorded instances of cyst of the vocal cord, the percentage is in favor of the female sex. It is not difficult—bearing these facts in mind—to see how readily they may be confounded, if rational signs alone be considered, and the evanescent character of the laryngeal tumor, probably rarely forcing the patient, on account of increasing vocal distress, to an early examination. No direct inspection of the larynx is considered necessary, and refuge is taken in that most comforting and convenient shelter in time of diagnostic doubt—hysteria—until the sudden restoration of voice in the previously aphonic patient dispels any lingering suspicions and apparently confirms one in his mistaken diagnosis.

I am willing to admit that this supposition, so far as it concerns diagnosis, is somewhat hypothetical, but at the same time the question that I raise has its practical bearing.

Mrs. X——, aged thirty years, consulted me November 18, 1880, at the request of her family physician, Dr. A. H. Campbell, on account of a marked hoarseness, which had very suddenly commenced three weeks previously, and without known exposure or direct cause. It caused her uneasiness, but no local distress; interfered, however, very materially with the singing voice and, not passing away under the influence of the ordinary remedies which had been employed, determined her and her physician to seek further advice.

In an otherwise perfectly normal larynx, one unusually free from all catarrhal inflammation, I found, upon laryngoscopic examination, a small, spindle-shaped, perfectly translucent, smooth, shining tumor, looking exactly like a clear glass bead or drop of clear mucus, situated upon the edge of the right vocal cord, or rather curling over it, if I may be allowed the expression, at the junction of the anterior

and middle thirds. The cyst was not larger than a good-sized pin's head, and suffered no alteration in shape or position during the physiological movements of the larynx. Its location accounted for the interference with vocalization, preventing, as it did, perfect approximation of the free edges of the vocal cords.

There being no question as to diagnosis, although this was my first experience with a cyst in this locality, I explained to the intelligent patient that two courses were open to her so far as treatment was concerned: first, to allow the removal of the little growth with appropriate laryngeal forceps (either by crushing it or tearing away its wall, or by using the pointed laryngeal lancet to incise it; in either case experience proves that the sac rarely refills); and second, to leave it undisturbed until it had attained a certain size, when it would spontaneously rupture and disappear; that such was the natural history of the affection, the time of the latter occurrence being indefinite, but that there was no danger to her in delay. My patient naturally chose the latter alternative, and, as the result proves, not unwisely. On December 14th she returned to inform me that on December 9th her voice, after having been continuously and even progressively hoarse since the date of her first visit to me, had suddenly cleared—in a moment, as she expressed it—and had since remained good. A careful examination of the larynx failed to detect the slightest evidence of the former existence of the cyst.

Remarks.—I have alluded to the rarity of recorded instances, and presumably, therefore, of cases of cyst of the vocal cords. Cyst of the epiglottis, on the contrary, though very infrequent, can hardly be considered extremely rare (in 100 cases of laryngeal growth tabulated by Mackenzie, 2 were cysts of the epiglottis, and in a series of 50 cases of my own, 4 were cysts, all in the same locality—the present case is not included in this category), and constitute the one form of the disease which is alone alluded to in even the most recent works on laryngology. Cysts of the epiglottis are not, then, to be confounded with cysts of the vocal cords. Of the latter, Sommerbrodt has published a report of four cases, three of which he operated upon (one refilling and requiring a second and successful operation), and alludes to five others in which the diagnosis was doubtful. Such cysts of the vocal cords have likewise been observed, recognized as such, and successfully treated, according to Heinze—even before Sommerbrodt's article awakened renewed attention to the subject—by Gibb, in 1863; Merkel, in 1866; Fauvel, in 1869; and again by the same operator in 1873, in the case of a child, aged fourteen. Finally, Tobold had, up to 1871, observed nine cases, and operated upon five. Further evidence of the infrequency of laryngeal cysts in general (including those of the epiglottis, laryngeal ventricle, and vocal cords) is afforded by a glance at the statistics of different operators of large experience. The figures embrace intralaryngeal growths of all varieties of pathological nature. Tobold, in 206 cases of "polypi" occurring between 1861 and 1874, met with 21 examples of cyst (see above), of which 9 were operated upon; Fauvel, in 300 cases observed between the years 1862 and 1875, treated only 2 (see above). Mackenzie, in a record of the published cases of all observers, up to the issue of his classical essay, numbering 189, finds but 5 cases of cyst (Gibb and Merkel, alluded to above, Durham, Bruns, Johnson); and, finally, in his own series of 100 cases also, but 2 (of the epiglottis).

These figures, taken from the most accessible sources at hand at the moment, and by no means including a vast number of cases of laryngeal polypi of varied nature which may be found scattered through medical literature, will serve the purposes of illustration for which they are quoted, and certainly seem to prove the statement already made, that cysts of the epiglottis are rare, while those of the vocal cords are comparatively seldom met with. Finally, the most recent contribution to the subject is a case reported by Cervesato, together with the statement, concurred in by Zawerthal and Massei, that the presence of glands in the mucous membrane covering the vocal cords having been proved by recent observations, the etiology and pathology of cysts of this region has been fully explained. Sommerbrodt does not fully concur in this view, and I believe that he is in accordance with the majority of observers when he states that no glands are found *upon* the normal vocal cord.

Waldeyer has shown, however, that muciparous glands are found *below* the true cords and in the mucous membrane, which often have one or two openings at or near the lower edge of the vocal cord. The invariable location of the cyst on the edge of the vocal cord (though it may subsequently extend by growth upon the upper surface) is thus explained—by simple occlusion of the gland-duct.

It may be interesting to state, in conclusion, that Sommerbrodt gives the following signs as diagnostic of the affection: first, a nodular or spindle-shaped thickening of the edge of the vocal cord of the same white tendinous color as that of the normal cord; and second, its soft consistency, which permits of its indentation by the laryngeal probe, with an elasticity which serves to quickly restore its contour when the pressure is removed. Heinze adds that the sudden veiling and as frequent rapid improvement of the voice constitute a valuable sign, which the frequent repetition of the process, as in his reported case, only serves to confirm; and I would modify the statements of both authors by claiming attention especially for the peculiar translucent appearance of these little growths, an appearance which alone serves to distinguish them from the other varieties of intra-laryngeal neoplasm. The difficulty which has been alluded to of diagnosticating, in certain instances and by rational signs alone, the affection under consideration from hysterical aphonia, will be simplified by remembering one of the main characteristics of functional aphonia, viz., that though the voluntary power of phonation is lost, the reflex function is not affected, for both cough and sneeze are accompanied by a distinct phonetic sound, a condition that manifestly cannot exist when the mechanical barrier offered by the interposition of a laryngeal growth of the glottis prevents perfect approximation of the vocal cords. The certainty of diagnosis afforded, however, by the use of the laryngeal mirror, renders a further consideration of rational signs superfluous.

GUY'S HOSPITAL.—Dr. Hilton Fagge and Mr. Davies-Colley (having promised to obey the nurses) have been elected respectively Physician and Surgeon to Guy's Hospital, in place of Dr. Habershon and Mr. Cooper Foster, resigned.

ANOTHER MEDICAL DIGNITARY.—Dr. Alverenga, of Madrid, has been appointed member of the Privy Council, with the dignities of a royal councillor.

NOTES ON DISLOCATIONS OF THE HIP.

By WILLIAM T. BULL, M.D.,

SURGEON TO THE CHAMBERS STREET AND ST. LUKE'S HOSPITALS, NEW YORK.

(A paper read at the meeting of the New York Surgical Society, January 12, 1881.)

THE following cases of dislocation at the hip-joint have come under my notice at the Chambers Street Hospital within the past five years. The chief interest which attaches to them is the method by which reduction was accomplished, and I shall limit myself to the consideration of this point. I should say in advance that I have been indebted wholly to Bigelow's monograph for the ideas which I have put into practice.

CASE I.—A mechanic, thirty-three years of age, while wrestling, was thrown forcibly to the ground and sustained a dislocation of the left femur, on the dorsum of the ilium, presenting all the characteristic signs of that injury. Twelve hours later ether was administered. The patient being laid on his back on the floor, the knee was flexed and the leg firmly held between my left forearm under the calf and my right hand over the ankle. The thigh was flexed on the abdomen and rotated slightly outward, then abducted and extended. The head of the femur could be felt to pass to the edge of the acetabulum with the first three motions, but resistance was met when extension was attempted. This was the case in two trials. A third effort, with a little lifting up of the limb just before extension was made, was successful.

CASE II.—A laborer, fifty-four years of age, was hit on the back by an iron girder of the elevated railroad, while he was bending forward to pick up something from the ground. He sustained a dorsal dislocation of the right hip. Six hours later, under ether, the patient being on the floor, reduction was accomplished in one effort by flexing the thigh in the adducted position in which it lay, rotating slightly inward, then abducting as far as the perpendicular, jerking it quickly upward.

CASE III.—A laborer, thirty-six years of age, jammed between the spiles of a pier by a ferry-boat, was brought to the hospital an hour later with a dorsal dislocation of the left femur. Ether was administered at once, the patient lying on the floor and the pelvis being steadied by an assistant, and the head of the bone was replaced in one effort, as in the preceding case.

CASE IV.—A deck-hand, thirty-three years of age, while sitting on the rail of a ferry-boat, was struck on the back by another boat, and his knee jammed against a post or the rail. The right hip suffered a dorsal dislocation. I saw the man four hours after the accident, and asked the house surgeon, Dr. Wilkin, to reduce it by the method which was successful in the two previous cases. His first manipulation succeeded, and reduction was completed in twelve minutes from the time the etherization was begun.

CASE V.—A workman, thirty-one years of age, fell in front of a street-car. His left knee was caught by the platform and he was pushed along in front of the car. The left femur was dislocated on the dorsum of the ilium. After two hours I tried to reduce it, under ether, by the method above mentioned. The head of the femur could be brought to the margin of the acetabulum easily, but resisted every effort to lift it into place. I then circumducted the limb to lacerate the capsule more, and repeated the manipulation in vain. Both Dr. Wright, the house surgeon, and myself then tried flexion, followed by circumduction outward and rotation outward, both with and without the "jerking up." These efforts were made both while the patient was on the floor and when on the operating-table. In the latter position the second manœuvre was then practised by Dr. Murray, the junior assistant surgeon. As the head of the bone reached the margin of the acetabulum and resistance to extension was felt, the thigh was rotated alternately inward and outward while being lifted, and it slipped into place. Half an hour was consumed in these attempts.

In one of these five cases of dorsal dislocation, reduction was accomplished by flexion, circumduction outward and rotation outward with a jerk upward. One case, the last mentioned, required the further manipulation of free circumduction (to lacerate opposing capsular or muscular fibres), and a sort of rocking motion of the head on the edge of the acetabulum, which probably enabled it to slip by some portion of the capsule which had not been ruptured. In both cases the lifting up was apparently necessary in order to restore the head of the bone. This method of reduction has been frequently employed. Bigelow, who terms it the "rotation" method, especially insists on the value of this "upward jerk," both in this method and that by simple traction; and all five cases testify to the correctness of his views. In the three cases which were so easily reduced, this "upward jerk" was the prominent feature of the manipulation after flexion had been made. The thigh was flexed as it lay in a position of adduction, and carried as far outward as the perpendicular; then, on lifting it up, the head of the bone glided into place. In a sixth case the head of the bone could be felt lower down on the dorsum (in the sciatic notch).

CASE VI.—A sailor, thirty-four years of age, was jammed between two piles by a ferry-boat, while defecating. He was brought to the hospital immediately. The right limb was shortened one-half inch, the thigh lightly flexed, adducted and rotated inward, the knee resting on the opposite one. Two efforts were made by flexion, adduction, and lifting up, but the head of the bone slid into the thyroid foramen before it was lifted. On a third effort great care was taken not to carry the limb beyond the perpendicular, and it was easily jerked into place. This case illustrates the fact noticed by several writers, that carrying the thigh too far outward in reducing the dorsal dislocation is apt to produce a thyroid dislocation.

In all these cases the after-treatment was the same. A thick layer of cotton was bound firmly about the hip with a spica-bandage, which was changed twice a day. After a week or ten days, according to the amount of tenderness, massage was practised twice a day. At the end of two or two and a half weeks movements were permitted, at first on crutches, which were laid aside at the close of the third or fourth week. No impairment of the functions of the joint followed in either case.

CASE VII.—An instance of dislocation toward the perineum, with fracture of the great trochanter, occurred in a man who died after three days, from fracture of the base of the skull. A muscular workman, thirty-seven years of age, fell from the track of the elevated railroad to the ground. The precise manner in which his injuries were received could not be ascertained. He had a severe scalp wound on the top of the head, much contusion over the left hip, a superficial wound on the outer side of the left leg, just below the knee, and was greatly prostrated. The left thigh was rotated outward and lying on its

outer side, slightly flexed, so as to raise the knee about two inches from the bed, and so much abducted as to occupy almost a right angle to the median line. The knee was flexed, the foot reaching nearly to the opposite knee. The trochanter was much depressed, could barely be felt through the soft parts, but appeared to move with the shaft of the femur. A firm, hard prominence could be detected beneath the muscles to the outside of the ramus of the pubes and ischium, and about midway between the symphysis and tuberosity. It was proved to be the head of the bone on displacing it slightly by moving the knee up and down. Two hours later the patient was conscious, with a good pulse and regular respiration, but restless. He was put under ether, placed on a table, with the pelvis resting on its edge and grasped by an assistant. A number of efforts were made to reduce the dislocation by flexion and circumduction inward, lifting up, and then extension. The head of the bone moved readily to beneath the acetabulum and back to its original position. Finally, in trying to depress the knee (extension), or to pry the head of the bone upward while it was steadied by the Y-ligament, it was reduced. This manœuvre was repeated several times with both inward and outward rotation before it succeeded, and I am unable to say in which direction it was rotated at the moment of sliding into place. It was then found that the trochanter was movable, with bony crepitus, when it was grasped and pushed backward and forward, and a fracture through it, in a vertical direction, was diagnosticated. A few hours later the man regained consciousness, and was less restless, but gradually relapsed into a condition of coma, and died on the third day. The cause of death was found in a fracture extending across the posterior fossa of the base of the skull, with extensive laceration of the frontal and sphenoidal lobes of the cerebrum. The left hip exhibited, externally, merely a slight ecchymosis over the trochanter major. Extravasated blood was found in the subcutaneous tissue of the groin and about the trochanter, and an extensive clot under the fascia lata, between the rectus and the cruræus muscles. After dividing the sartorius, rectus, tensor vaginæ femoris, adductor longus and pectineus, extravasated blood was found between the pectineus and psoas, and the contiguous fibres of the latter muscles were lacerated, and through the rent the head of the bone could be felt. The psoas and iliacus and adductor brevis were next divided, and the capsule of the joint found lacerated beneath them. Under the glutæus was more extravasated blood, but the glutæus medius and its underlying muscles were uninjured. It was then seen that the trochanter major was fractured through a plane running from the junction of the neck and trochanter almost vertically downward to the inferior border of the trochanter. The portion of bone thus separated included the attachment of the glutæus medius and minimus, the pyriformis, obturator internus and gemelli, and obturator externus, and the greater part of outer branch of the Y-ligament. The periosteum, strengthened by the aponeuroses of insertion of the muscles, held this fragment so firmly that only a slight antero-posterior motion, with separation of the fractured surfaces to the extent of one-eighth of an inch, was possible. On flexing the thigh and circumducting it outward, the head of the femur came through the rent in the capsule and through the upper fibres of the obturator externus muscle, till it reached the innermost edge of the thyroid foramen, overlapping the descending ramus of the pubes, a portion of its circumference touching the horizontal ramus. The ruptured ligamentum teres pointed directly upward, and the thigh assumed the position in which it was first seen, abducted to a right angle, slightly flexed, and rotated outward. The manipulation which accomplished reduction before death, was repeated; but it was found that, after bringing the head of the bone to the lower edge of the acetabulum—that is, after flexion and circumduction inward had been made, and while the thigh was held flexed nearly vertically upward—it was easily replaced by pushing it from below upward and outward. [This manœuvre at the time of reduction, attempted by either drawing on the thigh by a towel or loop of bandage, or by having an assistant push or pull on it, would have undoubtedly hastened the process, since the separation by fracture of the portion of bone to which the obturator internus and outer branch of the Y-ligament are inserted, rendered these structures less effective than usual in the effort to pry the head over the edge of the cavity.] The uppermost fibres of the obturator externus were torn through and separated from their attachment to the obturator membrane. After dividing all the muscles, it was found that the rent in the capsule started from its attachment to the edge of the acetabulum, half an inch inside of the anterior inferior spine of the ilium, and passed along the brim of the acetabulum to just beyond the trochanter minor. The Y-ligament was intact, also the acetabulum, but the fatty tissue at its bottom was infiltrated with blood.

I was able to secure the femur only, which I present for your inspection. It seems to me rational to conclude that the trochanter was torn off at the moment of displacement by the traction on its muscular and ligamentous attachments.

A SUCCESSFUL CASE OF TRANSPLANTATION OF SKIN ACCORDING TO WOLFE'S METHOD.

By EDWARD T. ELY, M.D.,

NEW YORK.

It seems desirable to record the successful results of skin-grafting according to Wolfe's method, and I can add one to those already reported by Wolfe, Wadsworth, Noyes, Matthewson, Howe, Zehender, and Aub.

My patient was a man aged fifty, whose face and eyes had been burned in a powder explosion. The right eye was lost. In the left eye the lower conjunctival cul-de-sac was obliterated, and the lower eyelid (which was cicatricial) was adherent to the globe so as to cover most of the cornea. Through the narrow strip of cornea which remained free the patient had good perception of light when the pupil was dilated with atropine.

On September 30, 1880, the lid was separated from the globe, so as to restore the normal space. A piece of skin a little more than an inch long and three-fourths of an inch wide was taken from the patient's forearm. It was applied to the raw, inner surface of the lid, and a few sutures were used to aid in keeping it in place. The dressing was cotton and a bandage. The graft united by first intention along the edge of the lid, and no sloughing occurred, except of a small point at one end. A thin superficial pellicle was exfoliated from the entire outer surface. The sutures were removed October 5th and 6th. I was unable to prevent the lower edge of the

graft from being gradually crowded upward in the subsequent cicatrization, so that the final result was to enlarge the exposed portion of cornea by only a small area, and this has never become clear enough to be of much use. The patient's eye is more comfortable, but he has not vision enough to go about alone. An upward iridectomy may improve it. But, so far as the vitality of the graft was concerned, the success was very gratifying. No antiseptic precautions were used, and in holding the skin over the end of my finger to scrape off the fat and cellular tissue, it was rather roughly handled, and dropped twice upon the floor.

I have employed this method once in operating for ectropion, and the graft (which was larger than the one described above) sloughed almost entirely. The patient was a very young boy, who could not be kept quiet or be prevented from crying after the operation.

In the case of a woman with symblepharon in Charity Hospital, I operated by transplanting a piece of conjunctiva, about half an inch square, from a man's eye affected with panophthalmitis. The graft lived. I thought that the hyperæmic condition of the transplanted conjunctiva was perhaps a favorable influence. The result for the symblepharon was only partially successful.

Progress of Medical Science.

The Physiological Action of the Active Principle of Piscidia Erythrina (Jamaica Dogwood).—Dr. Isaac Ott has undertaken a series of experiments with the active principle of Jamaica dogwood, which demonstrate the narcotic properties of this drug (*Archives of Medicine*, February, 1881). The following are his conclusions: 1, piscidia is a narcotic; 2, it does not paralyze or excite the motor nerves; 3, it does not act on the extremities of the sensory nerves, but their central connection—the sensory ganglia of the spinal cord; 4, it produces convulsions, partly by stimulation of the spinal cord and partly by heightened excitability of the voluntary striated muscles; 5, it reduces the frequency of the pulse by an action on the heart itself, probably on its muscular structure; 6, the arterial tension temporarily rises by stimulation of the vaso-motor centre—soon, however, it falls, which is due to a partial paralysis of the centre and of the heart itself; 7, it at first contracts and then dilates the pupil.

The Physiological Action of Conium Maculatum.—At a recent meeting of the Académie des Sciences (*Bull. général de Thérap.*, p. 365, 1880), M. Bouchefontaine alluded to the fact that in 1878 he had, in connection with M. Tiryakian, presented a paper on conium maculatum which went to show that hemlock owes its properties to two active principles—one, conine or cicutine, paralyzing the central nervous system, the other acting like curara. In 1879 M. Prévost, of Geneva, presented a note to the academy, in which he considered the bromhydrate of cicutine as a paralyzer of the motor nerves.

Bouchefontaine, by recent experiments, has satisfied himself that conine diminishes or abolishes the physiological properties of the nervous centres before acting, like curara, on the nervo-muscular cement substance (*substance jonctive*). On the dog and frog this alkaloid always ends by abolishing the nervous excito-mobility, provided it be given in sufficient quantity; but it is then fatal to batrachians and mammals. Its action is therefore different from that of curara. The effects of the bromhydrates extracted from hemlock in a crystallized condition are as follows:

They are to be divided into two groups: one is composed of amber-colored crystals, is more toxic than the other, acts like conine, and represents the most active principle of hemlock; the other variety of crystals, which are less poisonous, are colorless or of a pearly lustre, and resemble those obtained by Prévost. They act differently, however. As to the comparative action of hemlock and curara it may be formulated thus: hemlock may act like curara, but it produces, in addition, certain physiological effects not observed in animals to whom curara has been administered.—*Philadelphia Medical Times*, January 15, 1881.

The Communicability of Secondary Syphilis.—In a paper read at the St. Louis Medical Society Dr. Maughs (*St. Louis Medical and Surgical Journal*, January, 1881) elaborately discussed certain points relating to the pathology of syphilis. His views are in direct opposition to those entertained by the Hunter-Ricordian school of syphilographers and held by the majority of the profession. Maughs thinks that, 1, secondary syphilis is communicable as secondary syphilis; 2, that the accidents of secondary syphilis may be transmitted from a diseased to a sound person by contact of the secretions, without abrasion or lesions of surface, and, as a law, such accidents are transmitted in kind; 3, that when lesions do exist at the point of contact, such lesions are not chancres.

Syphilis as a Cause of Locomotor Ataxy.—In 1878, in a paper read at the Bath meeting of the British Medical Association, Dr. Gowers expressed the opinion that syphilis must be regarded as a cause of locomotor ataxy in one-half of the cases of that disease. Since then the subject has received much attention at the hands of Erb, Westphal, Remak, and others. In the *Lancet*, January 15, 1881, Dr. Gowers offers thirty-three cases of the disease in men as some evidence in support of his assertion, made in 1878. Of this number twenty-three (about seventy per cent.) had suffered either from a primary sore or secondary symptoms, and in fifty-three per cent. there had been undoubted constitutional symptoms, of which, in several, the indications were still present. The significance of these facts depends on the proportion of the male population of the county who have had primary sores, or constitutional syphilis. Before assuming a causal relationship in these cases between the antecedent venereal disease and the subsequent locomotor ataxy, we ought to deduct from the coincidences that proportion which the prevalence of venereal disease may have rendered accidental. Unfortunately, we have not the necessary information, but it is probable that the proportion of adult males, over twenty-five, who have had venereal sores, or symptoms of constitutional syphilis, is much smaller among the middle classes than among the poor. It is therefore of interest to inquire whether syphilis precedes ataxy with equal frequency in the two classes. Of the thirty-three cases, twenty-one were seen in hospital practice, and twelve in private. Of the former there was a history of constitutional syphilis in ten, and of a venereal sore alone in five, making a total of two-thirds of the hospital cases. Of the twelve cases seen in private, there was a history of secondary syphilis in eight, and of a venereal

sore alone in one, a total of three-fourths of the cases. These facts suggest that syphilis is an antecedent of ataxy, at least as frequently in the well-to-do classes as among the poor.

As a rule, the interval between the syphilis and the first symptom of the ataxy is considerable. It was noted by Erb in only seventeen cases. In five it was between two and five years; in eight between six and ten; in four between eleven and fourteen. In Gowers's cases the exact interval was, as a rule, longer than in Erb's cases. No case of simple tabes was met with earlier than seven years after infection, the actual numbers being: at seven years, one; at nine, three; at ten, two; at thirteen, three; at fourteen, two; at fifteen, one; at seventeen, one; at twenty, three; at twenty-one, one; at twenty-five, one. Thus two-thirds of the cases occurred more than ten years after the primary disease.

Treatment of Sprains by Massage.—Dr. Berenger-Ferand (*L'Union méd. du Canada*) has treated successfully some four hundred sprains with massage. His method consists of gently manipulating the injured part (the foot for instance), beginning at the toes and making passes as lightly as possible, with the pulp of the four last fingers, anointed from time to time with olive oil, on the dorsal surface of the foot, going from the root of the toes to the leg, following the direction of the extensor tendons. These frictions, which ought always to be directed from the extremity toward the root of the limb, and never in a contrary direction, are to be very gentle. They begin quite far above the painful part, and are prolonged as far below. They ought not to be painful, and in the cases in which, in spite of their gentleness, the subject finds them too painful, it would be necessary to begin at some remoter region. Little by little the pressure is augmented, and after some time, which varies from one to five minutes, friction may be applied with greater and greater force, and soon strong pressure no longer provokes pain. A *seance* ought to continue until all feeling of distress and pain have disappeared. When the operation is once terminated a retentive apparatus is applied.—*Monthly Review of Medicine and Pharmacy*, January, 1881.

The Radical Cure of Varicocele.—Dr. Henry Lee read a paper before the Royal Medical and Chirurgical Society (*British Medical Journal*, January 22, 1881) on this subject. The operation advocated was that of removing a portion of the anterior skin of the scrotum, and subsequently dividing the veins which were to be obliterated. All the steps of the operation were conducted through the wound made by the removal of the skin. The veins were compressed temporarily so as to prevent hemorrhage, and then divided. The cut orifices of the veins were sealed with the black, hot cautery which, if of proper temperature, was allowed to adhere to them for five or six seconds. The ligatures and needles used in compression were then removed, and the edges of the skin brought into apposition from below upward by carbolized sutures. Union by first intention took place more or less perfectly, and the patient was allowed to follow his usual avocation in three or four days. The risk of septic poisoning was obviated by the use of the actual cautery, which closed with the veins and the arteries, though the latter often required to be pulled out that the cautery might reach them. He had never seen sloughing in his cases; there was no difficulty in healing the wound of the scrotum.

The Tuberculosis due to the Inoculation of Indifferent Substances.—In a communication to the *Société de Biologie*, some time since, M. Martin claimed that the histological structure of tubercle nodules was devoid of special significance, since inoculation with indifferent foreign bodies produces the same anatomical lesions as those obtained with tuberculous matter. The pseudo-tubercular eruptions thus produced, in no way differ in their anatomical arrangement from the bodies held to be characteristic of genuine tuberculosis.

M. Martin then sought to determine whether or not the tubercles produced by the inoculation of tubercular matter differed in other respects from those following ordinary inoculations. He found that the tubercles of tuberculosis possessed the property of infection, whereas the pseudo-tubercles lacked this quality (*Gaz. méd. de Paris*, January 22, 1881).

It was ascertained that in a series of consecutive inoculations on different animals the infective properties of the original tuberculous matter became more and more active. In this respect it resembles the virus of septic processes, which Davaine has ascertained to acquire additional virulence with every repetition of inoculation on a new animal. The tubercles of indifferent substances acted in an entirely different manner. No matter how much of such material was employed, the lesions produced were merely local in extent. This was invariably observed. In no case did any tendency to generalization manifest itself, and not even the neighboring vessels and lymph-glands became inflamed or showed tubercular changes.

The non-infectious nature of pseudo-tubercles was best shown by attempting serial inoculations. The second animal subjected to inoculation from the pseudo-tubercular matter of the first, showed scarcely a local lesion, and the third showed no effects at all. It appears, therefore, that in addition to the true or infecting tubercle, there exists a second kind of granulum, anatomically identical with the former, but totally devoid of all specific properties.

Certainly this is another important contribution to our knowledge of general pathology, and it seems to corroborate Cohnheim's previous assertions concerning the infectious qualities of tuberculosis. Martin is apparently ignorant of the work of Cohnheim, but this makes his results and conclusions all the more valuable, because they were evidently obtained independently of the German pathologist.

Inflammation of the Lachrymal Gland.—From a study on inflammatory processes involving the glandula lacrymalis, D. Galezowski (*Recueil d'ophthalmologie*, February, 1881) draws the following conclusions: 1st, inflammation of the lachrymal gland is a very rare affection, but when it occurs it has almost the character of an epidemic; 2d, the most characteristic symptoms of the disease are swelling at the border of the lid and partial chemosis at the extreme angle, tumefaction at the cul-de-sac, engorgement of the lymphatic glands of the parotid region, and peri-orbital neuralgia; 3d, antiphlogistic treatment, scarifications where chemosis exists, in conjunction with preparations of iodine, are amply sufficient to establish a cure and prevent complications from participation of the eyeball in the inflammation.

An International Congress of Electricians is to be convened at Paris.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 12, 1881.

THE JEOPARDY OF SCHOOL CHILDREN.

THE deplorable unsanitary condition of Grammar School No. 17 of this city has at last awakened public attention. For a long time sewer-gas has found its way into the classrooms, and teachers and children have been sickened in consequence. The condition of affairs to which we refer was duly reported to the Board of Education two years ago, but in consequence of a method of procrastination peculiar to that body when sanitary reforms are to be considered, nothing has been done. Now, however, that the amount of sickness in the school is so great, and, on the general principle that "the last straw breaks the camel's back," even the Committee on Buildings are beginning to unwind some of the red tape that has for so long a time hindered the necessary repairs to the building. Of course no one is to blame save the poor children who get sick. The Board of Education, with its various committees, the inspectors, the trustees, and other school officials, make up a ring, of the responsibility of which there is no beginning or end.

The *New York Herald*, which has been tireless in its efforts to bring about reform in the sanitary management of our schools, thus tersely and truthfully describes the present disgraceful condition of affairs:

"It is true that those class-rooms are the habitation of four thousand children and their teachers six hours a day, and five days in a week; it is true that several teachers have been prostrated and that the children have suffered to an indefinite extent from these gases; it is true that this condition of affairs was understood by the Board of Education and the ward trustees two years ago; true that a contract for making the necessary improvements was prepared at the time; true that it was never executed; true that the Board of Education again 'has the subject under consideration.' But it is equally true, as was originally asserted, that Grammar School No. 17 is a long way off from repair. When the Board of Education 'has a subject under consideration' it means that at some future period of time, after this committee shall have consulted with that committee, and that committee has reported to the Board of Trustees, and the Board of Trustees have communicated with the Board of Education, then the party of no part —*i.e.*, the Board of Education—will authorize somebody to do something—always provided, in the meantime, that nothing has transpired to interfere with the evolutions of the official tape. If any of the four thousand children or their teachers are physically unable to await the consummation of these decent and orderly proceedings, so much the worse for them."

And yet all this culpable inactivity exists with our school board in the face of the oft-repeated assertion on their part, that there is no need for sanitary inspection of our schools, that the school committees are competent to attend to the health of the children, and that the class-rooms are in good sanitary condition. We have repeatedly shown that this has not been the case; that the schools are, as a rule, in bad sanitary condition, in that they are overcrowded, improperly heated, badly ventilated, deficient in light, and very often permeated by the foul and noxious gases of the sewers. There are other schools than No. 17 that demand attention. In fact, it will be difficult to find a single class-room which does not need the visit of a sanitary inspector.

Although on one hand it is deplorable that so many children and teachers should suffer from the neglect of school officials, it is a matter of congratulation that they have suffered in a good cause; that by such widespread sickness public attention has been aroused, and that at last the necessary steps may be taken to remedy the evils.

In the meantime, however, the school should be closed; nor should it be reopened until a thorough inspection is made by the Health Board, and a suitable guarantee that all the defects in sewerage have been permanently and effectively remedied. While this is being done, let the Health Board send its inspectors into other schools, and learn how many matters pertaining to the health of the scholars require immediate attention and prompt action. It does not appear that relief can come from any other quarter. If anything has been demonstrated in the recent discussions concerning school hygiene, it is that the Board of Education is not only incompetent to deal with the great question, but culpably obstructive regarding the efforts of all others who have the health of the school children at heart. Year after year bills have been introduced into the Legislature for the sanitary improvement of the schools. These bills have been repeatedly defeated by the efforts of members of the Board of Education. This board has time and again solemnly declared that it could easily attend to health matters connected with the schools, and this is one of the ways in which it does it.

HEAT-PRODUCTION AND THE THEORY OF FEVER.

The existence or not of an inhibitory thermic centre is a matter which has more of physiological than of practical interest. Such is not the case, however, with the question whether there is increased heat-production in fever, and of the relation of this heat-production to its dissipation; for the solution of this problem has a most important bearing on the treatment of febrile conditions. It has been asserted by Liebermeister and Leyden that there is increased heat-production in fevers, and that this causes the rise in temperature. Traube, on the other hand, contends that heat-retention is the great factor. Certain American observers, Walton and Witherle, showed very ingeniously the errors in Liebermeister's experiments, and deduced the conclusions that heat-retention was certainly a prominent factor in the febrile rise of temperature. Dr. Wood, by a large number of experiments, confirmed and greatly elaborated this latter view. He induced septic fevers in dogs and rabbits. He then measured their heat-production upon various diets, and when starving. The heat-production was also measured in healthy dogs, both when on a rich animal diet and when fasting. It was found that a dog on a low diet produced more heat when in a fever than when its temperature was normal, the diet being the same. But the amount of heat produced in fever on a low diet was generally less than that produced in health on a rich diet of animal food. These conclusions are corroborated by evidence obtained in another way. An approximate estimate of the amount of heat produced in the body can be obtained by comparing the heat-value of the food ingested with its chief ultimate products—urea, carbolic acid, and water. This mean heat-production, in a man of average size, living on an adequate diet, is two thousand two hundred kilogram units (Ranke). Now, further calculations of the heat production, under various conditions, show that in fever, on a low diet, it averages less than the above amount, though it is more than the heat-production in health on this same low diet. These studies also seem to prove that in fever the overplus of heat is produced chiefly by a consumption of the tissues, *i.e.*, of tissue-albumin, especially the protoplasm of muscle and blood-corpuscle. On the other hand, the overplus heat produced in health by large amounts of animal food comes from a consumption of this excessive food, after it has been turned into the albuminous constituents of the blood-corpuscle and plasma (forming "store-albumin"). There appears to be a tissue-heat and a food-heat, the former rising in fever, the latter in health, under a rich diet.

Both deductive reasonings, based on the heat-value of food and direct experiment, lead them to this conclusion, which Dr. Wood believes to be demonstrated for dogs, and practically assured for man:

"Fever is a complex nutritive disturbance, in which there is an excessive production of such portion of the bodily heat as is derived from chemical movements in the accumulated material of the organism, the overplus being sometimes less, sometimes more, than the loss of heat-production resulting from abstinence from food. The degree of bodily temperature in fever depends, in greater or less measure, upon a disturbance in the natural play between the functions of heat production and heat-dissipation, and is not an accurate measure of the intensity of increased chemical movements of the tissues."

According to this, of course, the temperature may be normal, although an increased tissue-metamorphosis is going on. On the other hand, there may be a high temperature when the heat-production is actually less than normal. Any practical inferences from these propositions must as yet be made with caution. It is probably true that increased heat-retention (by a tetanus of the peripheral blood-vessels?) will cause increase of heat-production and a rise of temperature. On the other hand, the use of cold baths to dissipate heat will often cause an increase in its production.

The antipyretic effect of quinine, the salicylicates, alcohol, and similar drugs, act, most likely, by lessening tissue-metamorphosis, and, consequently, tissue-heat. But agents of this kind affect only one of the factors in producing temperature-rise. Plainly, there are not yet enough data to lay down the ideal antipyretic treatment. But the use of quinine or some similar drug, and of cool or tepid spongings, or wet coverings, is most in accordance with our present knowledge of the mechanism of heat-production.

The concluding portion of Dr. Wood's work is devoted to demonstrating what his previous experiments had led up to—the neurotic origin of fever. The genesis of septic fever very well illustrates this theory. Septic fever is produced by a poison circulating in the blood and acting upon the nervous centres. It is demonstrated that in septic fever the elevation of temperature is brought about almost entirely by the retention of heat. This retention can only be produced through the intervention of the nervous system, no conceivable influence of the poisoned blood upon the general protoplasm being able to cause the superficial capillary contraction to which this retention must be in a measure due. The fever of septicæmia must, therefore, be neurotic in origin. Stated more fully, the theory of the origin of fever is this: a poison circulating in the blood depresses or benumbs the inhibitory thermic centre, and consequently tissue-change and heat-production are increased. At the same time the vaso-motor centres are so affected that they do not provide for the normal dissipation of heat, and the temperature consequently rises. In some cases of sudden and

excessive fever, as in one form of the so-called cerebral rheumatism, the enormous and almost instantaneous rise of temperature appears to be due to a complete paralysis of the nervous centres presiding over heat-production and heat-dissipation.

The above is stated as a "theory of fever." A simple recital of deductions, however, can hardly do justice to what has been made by Dr. Wood's laborious experiments much more than a plausible hypothesis.

HUNTER'S POINT NUISANCE.

The Sanitary Committee of the State Board of Health have been busy for some time past in investigating the Hunter's Point nuisance. Much testimony has been accumulated tending to prove that Hunter's Point is accountable for the noxious vapors that so frequently pervade the atmosphere of Murray Hill. It seems almost ludicrous to believe it necessary to take testimony on this point. There is no difficulty in obtaining the necessary facts. The trouble will be in abating the nuisance. The Hunter's Point stench propagators are influential in many ways, and have thus far been able to evade every law created for their suppression. The State Board of Health has an opportunity now offered to it of abating the nuisance, and thus proving its usefulness. Let us hope that good will come of its present effort. The nuisance in question is just one of those which come under the jurisdiction of the State Board. If the latter is incapable of suppressing it, the people will have to content themselves by falling back on the good promises of the Health Board of the city, which, judging from past experiences, will be equivalent to giving up in despair.

BELLEVUE HOSPITAL MEDICAL COLLEGE.

Several weeks ago the Faculty of Bellevue Hospital Medical College assembled its students together and announced that the plan of having a three years' course would be abandoned. It was with great regret, they said, that a project which had been so long and widely advertised was abandoned, but the number of new students since last fall was only fifty, and at that rate of decrease the college would be unable to sustain itself. The faculty having made this sad announcement, retired—which was decidedly the best thing they could do. We now have, therefore, in all the colleges of this city, except the Woman's, the old-fashioned two years' course again.

There are very few who will learn of this relapse of the Bellevue College without feeling a keen regret, and perhaps some contempt at the performance. For it is certainly a discouraging check to the cause of educational reform. And even the friends of the college cannot be proud of an institution which, having "put its hand to the plough," has so suddenly and ignominiously turned back.

When it was decided by the faculty to introduce a three years' graded course into the college, we still remember with what firmness the plan was announced, and with what moral intrepidity it was asserted that the cost had been counted and that no discouragements could interfere with the execution of a project that would be of so much value to the American medical student. Yet before the first term of trial is two-thirds out, this beautiful conception is given up. It attracted the imagination, but not the students. By this course the college has unquestionably injured its reputation and lessened the respect which will be felt for it. It may claim that the profession did not support it, and that the other schools only gloated over its diminished numbers. Such cannot be taken as an excuse for the course taken. Considering the "generous rivalry" for large classes, this feeling should have been duly anticipated and bravely met. The plan should either not have been tried at all, or it should have been adhered to for a longer time. To have given in at the end of a paltry three months is simply contemptible. It will now appear to all that the learned but cautious faculty became badly frightened, and, being very weak of knee, they skipped back with rapid steps into their old courses. Toll the bell then for another "good intention" gone, for another lofty purpose shrivelled in an unthrifty soil. Write as its epitaph that Bellevue tried to be better than its neighbors, but it lacked the stamina and returned from a moral to a commercial basis, leaving behind its high resolves. Learn from its action that money seemed better than educational elevation, and students than medical reform.

The outlook for medical education is at present very discouraging—in this city at least. There is hope, we are told, in the West. New York, though still a great medical centre, and a place unrivalled in its advantages for studying medicine, is so to a large extent in spite of the medical colleges rather than because of them.

A BILL TO PREVENT THE ADULTERATION OF FOOD OR DRUGS.

Last October the National Board of Trade, in accordance with a previous advertisement, gave three prizes for the three best acts, accompanied by essays, designed to prevent injurious adulteration of food and drugs. A committee of this same board has now drawn up a bill based on those furnished by the prize essayists. This bill has been forwarded to Congress with a memorial praying for its passage. Its provisions are simple and deserve attention. Regulations preventing the importation of adulterated food or drugs are first made. In order to keep the country in general free from adulterations, certain special inspectors and public analysts are to be appointed by the Secretary of the Treasury from names submitted to him by the National Board of Health. Through the agency of these or other officers, the

National Board of Health is to make examinations of specimens of food and drugs collected in different parts of the country, and publish the results in its weekly *Bulletin*. If from the result of these examinations it is found that the law has been violated, the secretary of the board is at once to notify the proper United States District Attorney, who will institute proceedings against the offending parties. To prevent this law falling too severely in any case, the National Board of Health is authorized to publish from time to time a list of articles, mixtures, or compounds, declared to be exempt from the provisions of this act.

Reviews and Notices of Books.

Die Operative Gynäkologie mit Einschluss der Gynäkologischen Untersuchungslehre. Von Dr. A. Hegar, Prof. der Geburtshülfe, etc., und Dr. R. Kaltenbach, Prof. extr. für Gynäkologie an der Universität zu Freiburg i. B. Zweite Auflage. I. Hälfte. Mit 134 in den Text gedr. Holzschnitten. Stuttgart: F. Enke, 1881.

Operative Gynecology. By Profs. Hegar and Kaltenbach. Second edition. Part I.

The first edition of this work appeared in 1874, and rapidly established itself in Germany as a standard treatise on operations upon the genital organs of women. In fact, so large and comprehensive a work, specially devoted to this department of surgery, had not hitherto appeared in any language. The student or practitioner was obliged to glean his information from the ordinary text-books on diseases of women; and often the surgeon had to lose time in finding, among a mass of general information, the special directions needed for a particular operation. Hegar's book has, however, not been translated into English, and if we are not mistaken, is little known even to American specialists.

We have before us the much amplified first half of the second edition, and, as the reader can judge from the indication of the contents about to be given, in its present form the work will probably furnish the most complete exhibition of the various minor and major gynecological operations of any book on diseases of women, even including the excellent treatises of Thomas and Emmet. Of course, the present volume can in no sense replace such works, but it can justly maintain its position by their side. It may supplement, by a full account of technical details, whatever could find no place in other manuals, and, by systematically combining the scattered information found in the various monographs and journal articles, present a harmonious picture of gynecological surgery in its present advanced condition.

Indeed, this has been the aim of the authors, although it is not distinctly stated, there being no preface to the book. Of course, this manual can hardly be said to be suitable for beginners; but the specialist will scarcely wish to do without it, and quite particularly the American gynecologist, if he cares to obtain a very good idea of the status of his science as it obtains in Germany.

The first portion of the work deals with preliminaries, containing a complete account of the methods and objects of gynecological examinations. The authors prefer hard-rubber uterine bougies to spongetents, etc., for effecting the dilatation of the cervical canal. The different kinds of douches and injections, then the various pessaries, modes of practising tamponade, of cauterizing, of bandaging the abdomen, and similar every-day manipulations, are fully described. Artificial insemination is explained in a separate section; similarly uterine and general massage. Wound-treatment, and, as a matter of course in a German book, antisepsis, come next. The authors are not blindly enthusiastic advocates of the Lister method, and they consider the spray a dangerous rather than a beneficial precaution in all laparotomies (p. 193). The subject of ovariotomy is then fully exposed, and this section alone embraces 118 of the entire number of 386 pages.

Ovarian hernia is next considered from a surgical point of view, and then comes the topic of "castration," preferably called "oöphorectomy" or Battey's operation. Hegar wrote an exhaustive monograph on this subject, and he is therefore particularly well qualified to speak of its merits or demerits; for he alone has performed fifty such operations, with only seven deaths. The recorded cases of all other surgeons amount to 76, with 17 deaths. Thus, Hegar's mortality percentage was 14, while the conjoined average of all others amounted to 22.37 per cent. Hegar formulates precise indications and contraindications for oöphorectomy, and altogether it must be said that he has fairly weighed the pros and cons, the result being that he pronounces the operation safe, reasonable, and altogether desirable in certain well-marked cases of ovarian disease. This portion of the book closes the volume, and, though it is an exceedingly interesting subject, we must take leave of it here, hoping soon to see the work completed, with a second half as complete and excellent as its first.

A Practical Treatise on the Surgical and Medical Uses of Electricity, Including Localized and General Faradization; Localized and Central Galvanization; Electrolysis and Galvano-Cautery. By Drs. Geo. M. Beard and A. D. Rockwell. Third edition. Revised by A. D. Rockwell, M.D. With nearly two hundred illustrations. 8vo, pp. 758. New York: William Wood & Co. 1881.

This work has already established itself as a standard treatise on electricity, with special reference to the wants of medical men. The present edition, while not materially differing from the former ones, has nevertheless been improved in several respects. It has been the aim of Dr. Rockwell to condense wherever practicable, and the result has been to give much more information than was found in the previous issues, without any considerable increase in the bulk of the volume. We find that two valuable chapters have been added to the work, one on the sequelæ of acute diseases, and the second on exophthalmic goitre. It would appear from a consideration of the cases of Graves' disease cited in the volume, that general faradization may greatly benefit patients afflicted with this malady.

Other additions have also been made to the work, then the chapter on diseases of women has been amplified by the enumeration of interesting clinical points, and a satisfactory discussion of extra-uterine pregnancy from the standpoint of the electrologist. Taken all in all the book in its new shape will form a valuable addition to the library of the general practitioner, while it is almost indispensable to the physician who needs a competent guide to direct his electro-therapeutic manipulations.

A Treatise on Albuminuria. By W. Howship Dickinson, M.D., Cantab., F.R.C.P., etc. Second edition. Wood's Library of Standard Medical Authors. New York: Wm. Wood & Co. 8vo, pp. 300. January, 1881.

The present work is one of three written by the author upon "Diseases of the Kidneys and Urinary Derangements." It is intended to be a complete treatise upon albuminuria, or at least renal albuminuria. There are nineteen chapters all told, and they embrace a comprehensive account of the pathology, symptoms, and treatment of the various renal diseases associated with the presence of albumen in the urine. A special chapter is devoted to alcohol as a cause of diseases of the kidneys. The last chapter of the volume gives an interesting description of climate in relation to renal disease.

This second issue of Dickinson's works has been amplified by numerous additions to the text, and the insertion of many illustrations, some of which are quite good. The colored plate representing a pair of granular kidneys, does not give a very good idea of the characteristic appearance of this renal lesion. Scattered through the pages of the book numerous clinical histories, illustrating more or less typical cases of kidney trouble are found, and they give to this volume the character of an eminently practical treatise.

Recent literature is, however, not duly recognized, and as important contributions to the subject of albuminuria have been made within the past few years, the book is not fully up to the ideal of a modern treatise on renal diseases. Nevertheless it will repay a perusal of its pages, and as the leading views on treatment remain much the same as they were found a few years ago, the parts of greatest interest to the practitioner will be found useful, suggestive, and satisfactory.

The Bacteria. By Dr. Antoine Magnin, Licentiate of Natural Sciences, etc. Translated by George M. Sternberg, M.D., Surgeon U.S.A. Boston: Little, Brown & Co. 1880.

At the present time, when we hear rather more of micro-organism, germs, different cocci, in fine the host of vegetable particles known as bacteria, than the average mind-medical can digest, assimilate, and utilize, a work of the kind before us must be very welcome to the profession. Dr. Magnin is no enthusiast, his judgment is not warped by luxuriant imagination as to what great changes may be wrought by the myriad germs supposed to float everywhere in the air. He gives us merely a concise résumé of what we actually know regarding questionable little particles, not what some persons think they know and would have others believe to be true. As the translator has justly pointed out, this little work is written in a truly scientific spirit. Moreover, the author's lack of bias makes him a fair judge of conflicting claims, and makes him cautious of inferences and generalizations. This is nowhere better shown than in the list of conclusions found at the end of the subject-matter of the book. The severity of these conclusions we cannot refrain from giving in full, as indicating at once the fairness of the author's position. He says: "As to their rôle in fermentations, in putrefactions, in contagious diseases, and in surgical lesions, notwithstanding the considerable number of labors of which the bacteria have been the object in those different points of view, it is not yet possible to define it in a definite manner."

The value of this little work, so excellent in its way, is enhanced by a copious bibliography, brought up to date by the translator, who certainly deserves credit for his English rendition of a valuable contribution to a subject which daily interests and agitates the professional mind, sometimes completely capsizing its clear judgment, and often disturbing its delicate equipoise.

Reports of Societies.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 11, 1881.

Dr. H. B. Sands, President, in the Chair.

Dr. A. C. Post presented a patient on whom he had performed

ADAMS' OPERATION FOR THE RELIEF OF A CICATRICIAL DEPRESSION

on the face. The depression was the result of an abscess beneath the periosteum of the upper jaw and connected with disease of the teeth. After a tooth was removed the abscess healed, leaving the skin drawn down so as to form a depressed cicatrix. The operation, suggested by Mr. Adams, consisted in making a subcutaneous dissection and introducing two pins at right angles to the base of the depression, so as to keep the cicatrix elevated for three days. The result of the operation is to cause the cicatrix to remain elevated for a time, but it gradually subsides to its normal position. It seemed to promise well as an operation for the relief of such cicatrices on the face, especially among ladies. The cicatrix remains, but the depression is relieved.

Dr. Sabine referred to a lady who had two depressed cicatrices—one just below the left angle of the jaw, and the other in front, upon the same side of the neck, below the mental foramen. He operated upon the anterior one by excising the cicatrix and then sliding in a flap of skin, and the result had been so successful that the patient proposed to have the other one operated upon in the same manner. In that case Adams' operation could not have been done, because the skin was so thin that it would not have been possible to raise it properly, and a scar would still have been present.

Dr. Wm. T. Bull then read a paper entitled

NOTES ON DISLOCATIONS OF THE HIP.—[See p. 290.]

Dr. Markoe said that throwing the head of the bone over into the thyroid foramen, while attempting to reduce a dorsal dislocation by manipulation, had been quite a common accident in his experience.

Dr. Post had always found that, in such cases, it was easy to reduce the bone to its proper place by avoiding abduction.

Dr. Briddon thought this accident occurred much less frequently since Bigelow had brought forward his method than it did when the exaggerated movements were made.

Dr. Markoe said that Reid, in his original paper, stated that it was not necessary to abduct the thigh strongly in bringing it down.

Dr. Post had not seen evil result from the accident.

Dr. Markoe regarded it as somewhat embarrassing,

and to a certain extent it might do mischief by tearing up additional spaces.

Dr. Sabine referred to a case of ordinary dorsal dislocation of the femur, which he saw when house surgeon in the New York Hospital in 1865. He attempted reduction by manipulation and threw the head of the bone into the thyroid foramen two or three times. Finally it was necessary to resort to pulleys, and reduction was accomplished by the late Dr. Allin with a great deal of difficulty. In the following week he met Dr. Van Buren and mentioned the case, and the doctor remarked that the thigh ought not to have been carried out so far when the head of the bone was beneath the acetabulum, but should have been lifted up—the very manipulation which Bigelow emphasizes so much.

The President inquired whether any member had had an experience similar to that related by Dr. Sabine, where manipulation failed to accomplish reduction? He supposed such failure was rare. About fifteen years ago, as he then understood it, he was unable to reduce a dislocation by this method. The patient was a stout, muscular man, whom he saw in consultation with Dr. Frothingham. Dr. Sands did not practise the lifting movement, but resorted to ordinary manipulation, and, after spending some time, became satisfied that further efforts by that method would be unavailing. It was decided to use the pulleys, and Dr. F. arranged the apparatus, screwing the staple into the wood-work beneath the window. Bracing his feet against the wood-work, he pulled with increasing force until, suddenly, the staple was pulled out, and as the doctor tumbled over upon the floor the bone slipped into place.

Dr. Post remarked that in a large proportion of difficult cases reduction takes place, not while the extending force is being applied, but when sudden relaxation occurs after extension has been kept up for some time.

The President remarked that he was unable to recall a single case of recent dislocation in hospital practice in which an attempt at reduction by manipulation had failed.

Dr. Post remarked that he had not known it to fail.

The President inquired with reference to mischief following the treatment by manipulation. He remembered one patient who lost his life after reduction of the dislocation by this method. A man sixty-three or sixty-four years of age was admitted to the City Hospital in Broadway with a perineal dislocation, which was reduced by manipulation, and, it was thought, without the application of undue force. An enormous abscess, however, developed after the operation, and the patient died in consequence of the extensive suppuration that followed.

DISSEMINATED CANCER.

Dr. A. C. Post narrated a case as follows: On the 18th of December he was called in consultation to see a woman forty-nine years old, who had menstruated up to that date, and had enjoyed good health up to the preceding August, when she first noticed an induration of both breasts. When Dr. Post saw her in December, both breasts were extremely hard and closely adherent to the skin and subjacent parts. They were not painful, and were insensible to pressure. The right axilla was filled with hard deposit involving the skin, and the right arm, forearm, and hand were œdematous. There were some hard deposits in the left axilla, but it was not filled, and there was no œdema of the left upper extremity. There was œdema beneath the left clavicle, and there were numerous hard nodules in the skin of the trunk, face, and extremities. The indurated breasts were hemispherical in shape, and not more than eight centimetres in diameter. It was a case of disseminated cancer, and he regarded the condition of the breasts as quite remarkable because of the close attachment to the skin and subjacent tissues, and the parchment-like condition of the integument. He had never seen a case in which there was such extensive adhesion and excessive induration.

Dr. Sabine referred to a case sent to him by Dr. Van Buren, in which the patient had had her right breast removed for cancer about a year previously, and the disease had returned in her left breast, and she also had disseminated cancerous nodules over her chest and abdomen, varying in size from that of a pea to the end of his little finger. Dr. Peaslee also saw the case, and what was most remarkable in its history was that, two or three months before death, which occurred about fifteen months after the operation, every one of the supposed cancerous nodules disappeared and left a depression in the skin like a scar. There was absence not only of cancerous nodules, but of subcutaneous tissue. She died of internal cancer.

Dr. Markoe said that Mr. Paget spoke of the disappearance of myeloid tumor, as it had been observed in numerous instances. He also referred to a case in the New York Hospital, in which the patient died from tumors upon the head and side of the face, and in whom that history was repeated several times. The early tumors disappeared entirely. That case, however, was believed to be one of soft cancer, and not myeloid disease.

CYSTIC TESTICLE.

Dr. Sabine presented a testicle which he had removed from a patient forty years of age, who came to the hospital on December 31, 1880, with a swelling upon the right side of the scrotum. The swelling was soft on the inner side, rather firm on the outer side, elastic, not translucent, and the testicle could not be felt anywhere. The man gave the history of a hydrocele, saying that he had been tapped once or twice without special benefit. There was a thick sac-wall, and Dr. Sabin concluded to perform Volkman's operation or a modification of it. After the patient was etherized he introduced the needle of a hypodermic syringe and drew off a few drops of a fluid which was yellowish but not perfectly clear, and he supposed there was no doubt that the case was one of hydrocele. He then introduced a small trocar, intending to draw off all the fluid, but not more than four or five drops of fluid of the same character as that drawn by the hypodermic syringe was obtained. Another puncture was then made, but even a less quantity of fluid was obtained than by the first. He then made an incision, by suggestion, about an inch long, and after cutting through the tissue there protruded a number of small cysts, showing that the testicle was cystic. Not having consent to perform any operation except that for hydrocele, the patient was returned to his bed.

On January 11, 1881, Dr. Sabine removed the testicle, which had the appearance of a cystic adenoma. With reference to the different tappings and the amount of fluid drawn, the man gave the following history: Four years ago he had double hydrocele, which was treated by drawing off the fluid and injecting iodine. The hydrocele did not return on the

left side, but it reappeared on the right side, which was tapped the second time about seven months after the first tapping, and twice since, at the Massachusetts General Hospital. The last tapping was some eighteen months ago, at which time the tumor was about the same size it was just before the testicle was removed.

In the specimen there was no evidence of tunica vaginalis.

The history of previous tappings, and the close resemblance of the tumor to a hydrocele with thickened tunica vaginalis, led to the error in diagnosis.

METHODS OF TREATING THE CORD IN CASTRATION.

Dr. Sabine asked Drs. Markoe and Sands what they considered the best method of treating the cord in castration? Erichsen and Bryant recommended tying the cord *en masse*, while others believed it to be better to hook up the cord and divide it gradually, tying the blood-vessels as they are reached. Dr. Sabine adopted the latter method in his case, and considered it very much better than grasping the cord and cutting it off directly.

Dr. Markoe remarked that the method was regulated somewhat by the distance from the external ring at which the cord was divided. In cases in which he had complete control of the cord, and was at liberty to cut wherever he might choose, he had tied particular vessels, and then cut it with one sweep of the knife. But where he could not get that control, he had cut gradually.

Dr. Post referred to the practice of scraping off the cord in castrating pigs.

The President said that he had practised several methods. He had tied the cord *en masse*, and thought it an unnecessarily rude procedure, and in the single case in which he did it considerable inflammation followed, which, he thought, was due to constriction of the tissues; at a later period a slough of some size came away. He had secured the cord with forceps or a strong thread, divided it with one sweep of the knife, and then tied the arteries upon the face of the stump. The method which he preferred was that practised by Dr. Markoe. He usually put a ligature through the cord above, and then, taking the testicle in the palm of the hand and putting the cord upon the stretch over the index finger, divided the different layers in succession, and tied the arteries as they spurted. He thought the plan had the advantage of enabling the surgeon to secure every artery. He had sometimes allowed the string to remain in the cord for a day or so. He had adopted this expedient with advantage recently in a case of sarcoma of the testicle. The arteries were tied with catgut, and as they did not seem to be very tightly embraced, the traction-ligature was allowed to remain. In the course of the night hemorrhage occurred, one of the catgut ligatures having slipped, and the string through the cord above facilitated the ligation of the bleeding vessel.

Dr. Sands thought that Dr. Sabine's cautious procedure with reference to permission to perform the operation was commendable. He recalled a case in Bellevue Hospital. At a meeting of the medical board a man was brought in and placed against the wall, while the house surgeon was made to incise a supposed hydrocele. One long, deep incision was made, and the knife cut directly into a cancerous testicle. As the patient was not under the influence of an anæsthetic, his consent to castration was promptly obtained, and the testicle was at once removed.

Dr. Briddon thought the particular objection to tying the cord *en masse* was the time required for the ligature to come away. He referred to a case in which the ligature remained six months, and was then so firm that he was unable to pull it away. He had seen several cases in which the ligature remained several months before it came away.

Dr. Markoe remarked that, if obliged to cut the cord near the external ring, there was no other way except to tie it *en masse*.

The President said that he had divided the cord at the level of the internal abdominal ring without tying it *en masse*, but he opened up the inguinal canal.

Dr. Markoe said that was a resource, but one not commonly adopted.

Dr. Post presented a portion of a tongue containing an

INDURATED ULCER,

which he had removed by making a V-shaped incision. A ligature was passed through the tongue, so that after the mass was removed the stump could be drawn out for the purpose of securing the vessels.

CANCER OF THE MALE BREAST.

Dr. Post presented the breast removed from a man fifty-eight years old. It was cancerous. The patient became conscious of the presence of an induration four months ago. There was no history of traumatism.

CICATRICIAL CONTRACTION FOLLOWING A BURN.

Dr. Post exhibited a plaster cast of a hand that had been deformed by the cicatricial contraction following a burn. The middle finger had a denser band than the others, but all the fingers were drawn more or less into the palm. The patient was a girl eight years old, and the deformity had existed five years. Dr. Post operated by making multiple divisions of the cicatricial tissue in the palm of the hand. The band opposite the middle finger was divided in four places, the little finger, three, the ring, the index and thumb, each two. The incisions extended through the entire breadth and thickness of the bands to the soft tissue beneath. The fingers and thumb were then straightened and secured with adhesive plaster to a splint made of felt, adapted to the fore-arm, hand, and fingers, and stiffened behind with narrow strips of hoop-iron. The operation was performed four weeks ago, and the hand was almost perfect in shape. The fingers were completely straight. The wounds had all healed except one which was nearly healed. A slight induration remained in the palm of the hand. The patient had imperfect power of flexion, but extension was perfect. Passive motion was being practised. Dr. Post thought great importance was to be attached to multiple division of the cicatricial tissue.

Women's National Hospital.—The Women's National Hospital, designed for the treatment of women addicted to the excessive use of alcohol or narcotics, was recently chartered by the Connecticut Legislature. The Board of Corporators met on March 2d and elected the following officers: *President*, Dr. J. Marion Sims, of New York; *Vice-Presidents*, Dr. Frank H. Hamilton, of New York, and Dr. George B. Hawley, of Hartford; *Secretary*, T. D. Crothers, of Hartford. The trustees are leading physicians from ten different States. The hospital will probably be erected in Fairfield County.

CLINICAL SOCIETY OF MARYLAND.

Abstract of Proceedings for the Months of December and January.

T. S. Latimer, M.D., President, in the Chair.

CHEYNE-STOKES RESPIRATION.

Of three cases of this anomaly, reported by Dr. O. J. Coskery, the following summary represents the chief features.

First.—Man with apoplexy. On fourth or fifth day, when apparently getting well, Cheney-Stokes respiration appeared; he would lie quiet for a few seconds, then, on the commencement of the peculiar breathing, he would spring up in bed panting for breath. The pulse exhibited no variation. Death ensued within thirty-six hours. Fatty degeneration of the heart on post-mortem.

Second.—Woman, over sixty years of age, with second attack of apoplexy. As respiration increased in depth and frequency, pulsations diminished; could not be roused; died in forty-eight hours; no post-mortem.

Third.—Boy. No brain trouble; muscular twitchings always accompanied the incipiency of the breathing. Respiration ceased entirely for seven seconds, then commenced and reached its maximum in eight seconds, diminishing gradually for eight more seconds, and followed by the pause. Thirty seconds were thus consumed in each of the periods or intervals. Number of respirations per minute, 13. No increase in volume of pulse, but increase in its frequency as respirations increased.

Dr. J. W. Chambers had observed two cases: one in a girl poisoned by opium; death in eight hours. The other, in a case of crushed foot; here pulse quickened with respiration; death in twelve hours.

SECONDARY SYPHILIS AGGRAVATED BY MERCURY, AND RELIEVED BY IODIDE OF POTASH.

Dr. Theobald saw two cases of syphilitic iritis grow worse under the use (for several weeks) of biniodide of mercury and atropia; ulcers also appeared on the soft palate and tonsils. Cure was effected on substituting iodide of potash.

DOMESTIC LEPROSY.

Dr. I. E. Atkinson exhibited a patient with leprosy, *who had never been outside of the State of Maryland.* She lived in Baltimore until the age of sixteen, then moved to the Eastern Shore—a malarious locality. Married and has several children. Symptoms began eighteen months ago, during pregnancy, with yellow spots on thighs, which gradually spread to trunk, chest, back, neck and face, and finally arms. Numerous minute nodules, from the size of a pinhead to a pea are now apparent, scattered through the superficial portions of the skin. Conjunctivæ congested, mucous membrane of throat and posterior nares thickened and granulated. The spots are anæsthetic. The case is one typical of the tubercular form, but has not advanced sufficiently for the leonine appearance to be manifest.

Dr. F. T. Miles had seen several cases in Charleston. It is not confined to the poor, but affects equally persons of high social position.

SUCCESSFUL LIGATION OF BRACHIAL ARTERY FOR TRAUMATIC ANEURISM OF ULNAR.

The patient, a tall, muscular young man, was exhibited by Dr. T. P. McCormick. The aneurism appeared in July, 1878, in consequence of a stab received the month previous. Two months after, when operated on, it had attained the size of a fist. The wound healed without suppuration, but the ligature did not come away for a month. In two weeks after the operation the tumor had disappeared entirely. The radial on that side shows feeble pulsation as compared with the opposite side.

IODINE IN INTERMITTENT FEVER.

Dr. R. B. Morison reported satisfactory results from the use of this remedy, in ℥ xv. doses, administered in mucilage and water; since November 1st, all the cases applying at the University Dispensary, twenty-five in number, had been treated with it. Less than one-half had been heard from, which he took as an indication that the greater part had recovered. Only one case of iodism was observed—in a woman who continued it after the chill had been checked; in this case the symptoms disappeared on the disuse of the remedy. No other treatment is now employed for intermittent fever in the dispensary department under Dr. Morison's care. The idea was gotten from an article in *Braithwaite's Retrospect.*

Dr. R. Winslow said he had known of the influence of this agent in intermittent fever for a long time. His father had used it many years ago in North Carolina, employing a pill containing powdered iodine, gr., ¼, quinine, gr. ij., powdered sulphate of iron, gr. ½, and ipecac, gr. ¼; one of these pills to be given three times a day for one month, in obstinate cases.

LITHOTOMIES WITH PECULIAR FEATURES.

Dr. L. McL. Tiffany reported the two following cases:

First.—A boy, three years of age, with the usual symptoms of stone; could find none, however, with the sound. Six months afterward the examination was repeated, with the same result; nevertheless, a probable diagnosis of encysted stone in the upper part of the bladder was made. Eighteen months afterward the patient was again brought, when by jerking the sound upward and depressing the bladder above the symphisis pubis, the stone was detected. The lateral operation of lithotomy was then done, but neither forceps nor finger could be gotten on the stone. The bladder was then pumped full of water with a Davidson's syringe and the water allowed to flow away; by this means the stone was dislodged from its sac and fell to the floor of the bladder, and thus became accessible to the forceps.

Second.—Man, twenty-three years of age; symptoms of calculus from birth. On introducing a sound, the stone was struck before entering the bladder. No instrument, however small, could be gotten into the bladder. The sound being passed down so that its point rested on the stone, Dr. T. cut down upon it. He found two faceted stones, upon removing which, he could get his finger in the bladder, where he found a third one, two inches long and one and one-half inch wide; this was crushed with the lithotrite and removed piecemeal through the perineal opening. The urine was alkaline. The walls of the bladder were found encrusted with phosphatic deposit. The bladder was washed out with a Davidson's syringe, to get rid of the fragments. Four days after the operation the surface of the wound was found covered with phosphatic deposit. The urine was rendered acid by the use of benzoic acid,

and the bladder was washed out with a solution of dilute nitric acid. Both cases recovered.

Dr. B. B. Browne mentioned a peculiar case of a girl, eight years of age, who had a stone in her bladder four inches in length. It was thoroughly encysted and extended into the urachus, reaching from the urethra nearly to the umbilicus. On grasping it with the forceps to extract, the traction could be felt from the umbilicus downward. As she lived in the country, Dr. Browne insisted that she should be brought to town before undertaking any further operative procedures. This was not done, however, and she subsequently died from the effects of the vesical trouble.

CANCEROUS GROWTHS.

Dr. J. Shelton Hill read a paper upon this subject, in which he dwelt chiefly upon their histological characters. There is no specific cancer-cell, yet the cells possess a certain amount of diagnostic significance, depending upon their size, shape, and number of nuclei. Their variety of form is due to mutual pressure. They usually contain fat, which is due to retrograde metamorphosis. The cells are collected into alveoli, formed by intercellular fibrous tissue, which is dense and firm in proportion to its age and slowness of growth. Some pathologists maintain that they arise from epithelial cells only, and they bear a remarkable resemblance to these; but, on the other hand, cancers originate in tissues (as periosteum) where no epithelial cells are found.

Dr. I. E. Atkinson said: Formerly the term cancer related to the malignancy of the growth, not, as now, to its histological features. Lately it has been applied to carcinomata, in which epithelial elements predominate. It may last twenty years. It is difficult to determine where the benign ends and where the malignant begins. What makes a wart of the skin malignant? According to some authorities, the crowding of epidermic cells causes a change of direction of growth. The stroma is a secondary formation, due to the development of the cells and the resulting displacement; hence also arise the alveoli. The blood-vessels, passing along the walls of the alveoli, are pressed upon and destroyed, leading to fatty degeneration and ulceration. The new view (Thiersch, Waldeyer, Billroth) is very definite and beautiful, viz., that cancerous growths can only originate from epithelial elements, not from muscle, bone, etc. It seems to be confirmed by the fact that when it attacks the latter tissues they are always in continuity or close proximity to epithelial tissues. In scirrhus we have without doubt a new growth of connective tissue; to what extent the influence of this tissue, and to what that of the epithelium prevails, it is hard to determine. The so-called cancer-cells are not distinguishable from epithelial cells. There are certain sarcomata (as the alveolar) which it is not impossible to tell from carcinomata. According to Rindfleish, the wander-cell makes its way into the epidermis, and there undergoes epithelial contagion; it must come in contact with epithelial cells before it assumes the malignant phase of growth. What the cause of the connective tissue new-growth is Dr. Atkinson thought not definitely settled.

THORACIC ANEURISM.

Dr. R. B. Morison exhibited a patient, forty-one years of age, with the following history and symptoms: he was a bricklayer by trade; fifteen years ago he had syphilis. Last October a year, whilst stooping down in such a way that his knee pressed upon his chest, he felt a sharp pain, and shortly after noticed a pulsating tumor on the anterior surface of the chest. In consequence of this he was obliged to give up work. Eight months ago he came under the speaker's observation with a strongly pulsating tumor, having a distinct bruit, and situated at the junction of the third and fourth ribs, on the left side, with the sternum. Iodide of potassium was prescribed, the dose being gradually increased, until it now amounts to gr. lxxv. per day; compression was made by means of an elastic band, and rest on the back enforced (except when it was necessary to answer the calls of nature). Examination by the sphygmograph shows the carotid on the affected side to be uninvolved, which would indicate the location of the aneurism to be about the junction of the arch with the descending aorta. According to Tuffnell, a cure can almost be assured if the treatment by rest, etc., be thoroughly enforced. Should this fail, the speaker would resort to electrolysis; this seemed devoid of danger, and he had not found any author who had tried it and was opposed to it.

Dr. I. E. Atkinson had examined the urine of this patient and found it loaded with pus. There was no urethral trouble and the origin of the pus was not apparent, though the acidity of the urine would indicate an origin not in the bladder.

Dr. Morison referred to the theory of Myers that the great prevalence of aneurism in the British army is due to the collar worn by the troops. A medical friend, who attended the Paris hospitals saw no case of aneurism there during three years; yet on first reaching London he saw a case, and met five during a short residence there.

Dr. William Lee was inclined to attribute the prevalence of the disease in England to the absence of laws regulating prostitution.

Dr. R. W. Johnson urged the necessity of the most complete rest, both mental and physical, which it was possible to obtain. Stimulants of every sort should be prohibited. He suggested the use of the fracture-bed, so as to avoid rising during stool. The diet should be as light as possible. He thought a hospital no place for treating an aneurism. Electrolysis should be a last resort. He had seen several cases which were benefited by it. It must not be forgotten that mental perturbation is caused by the simple suggestion of puncturing with a needle.

CASE OF SUPPOSED MULTIPLE SARCOMA OF SKIN.

Dr. A. F. Erich reported the case of a gentleman aged seventy-two, who exhibited a number of small, round, generally firm tumors scattered over the surface of the body. They have existed for from nine months to two years, the greater number for the shorter period. Most are movable with the skin; some are purplish. There is no difficulty in removing them on dividing the skin overlying them; but in the case of two, removed by another physician before the patient came under Dr. E.'s care, a fungoid mass sprang up in the sites they had occupied.

Dr. I. E. Atkinson agreed with Dr. Erich in regarding this as a case of multiple sarcoma. It belongs to an interesting and unusual class. Kaposi reports cases of multiple melanotic sarcoma. Too much stress was laid on the prevalence of sarcoma in youth; he had seen many cases in advanced life.

Dr. John Morris had a similar case; one of the

tumors removed from the breast weighed eight to ten ounces. There was but little pigment in this case. The patient was a fine-looking and fat woman of forty-five.

HOT WATER AS AN ADJUVANT IN PERINEAL SECTION.

Dr. Tiffany reported the case of a boy aged fifteen, who fell a distance of fifteen feet astride a barrel, bruising and tearing the perinæum and scrotum so that blood trickled from a wound in the latter. Three hours after, the perinæum and scrotum became tense; no water had been passed since the accident. An attempt was made by a physician to introduce a catheter, but it could not be passed beyond the perinæum. Dr. T., being summoned the next morning, found the perinæum and lower part of the abdomen greatly swollen, with intense desire to pass water. He at once made an incision into the perinæum from the scrotum to the anus. The cavity thus exposed extended back to the rectum and up over the os pubis and anterior wall of the abdomen. The left pubic bone was found to be fractured. Much oozing of blood followed the incision, which was checked in a few seconds by the injection of hot water into the sac by means of a Davidson's syringe. The distal end of the urethra then became visible, through which and into the bladder a director was passed and the neck of the bladder incised as in the operation of lithotomy. Sloughing has since taken place, necessitating three openings over the abdomen. Three weeks and a half have elapsed, and the patient is still unable to walk, whilst all his urine passes through the perineal and abdominal openings. The interesting points in the case were: the necessity for opening the perinæum, the effect of the hot water upon the hemorrhage, and the ease with which the urethra was discovered. In the operation of perineal section it is exceedingly difficult to find the distal end of the urethra, and this was the only case in the speaker's experience in which he had found this possible.

CASE OF SUPPOSED ADVENTITIOUS GROWTH IN THE CEREBELLUM.

Dr. A. B. Arnold reported the case of a girl, twelve years of age, in whom vomiting began without assignable cause. This was followed by paroxysmal headache, situated in the occipital and right temporal region, which lasted twelve months; then defective vision began, terminating in total blindness. Ophthalmoscopic examination revealed double choked disk. A prominent feature in this case, and the one which chiefly led to the localization of the lesion in the cerebellum, was a tottering gait, the patient balancing herself by extending her arms. Westphal relates cases of lesions of the cerebellum exactly like this.

Dr. E. F. Cordell referred to a case in an adult, in which all the above symptoms were present, and, in addition, epileptoid convulsions and mental derangement. The patient was taken to his home in Belfast, Ireland, where he died in a few months from the intracranial trouble. No post-mortem had been made as far so he could learn.

HEADACHES OF CHILDHOOD.

Dr. William Lee opened this, the regular subject of discussion, by a carefully prepared paper. He said, that, as member of the School Board of Baltimore and chairman of the committee on health of same, he had been led to observe the common occurrence and frequent neglect of headache in children. It is apt to be hereditary, and is especially to be traced to confinement and over-study at a time of life when the brain is still undeveloped. Its causes in the class mentioned are, among others: 1st, overtaxing the brain; 2d, gastric and intestinal disturbance, worms; 3d, anæmia (from malaria, etc.), producing neuralgia or nervous headache.

Monobromide of camphor produced the best results, in the first variety, in the speaker's hands. Sick headache accompanies the second, in which the most effective agents are fluid ext. guarana (especially if the patient be kept at rest after using—a very important precaution) and nux vomica. The latter agent, as pointed out by Bartholow, is invaluable in these cases; it has been too much neglected by the profession. The third variety may be due to teething. A general tonic plan (in which valerianate of zinc may well be included) was recommended here. In malarial headaches, Fowler's solution and dialyzed iron give the best results.

Dr. J. E. Michael said one form had been omitted, viz.: "optical headaches"—those due to over-strain of the eye while developing. These may be due to defects of structure or over-sensitiveness, or to defective hygienic regulations (a frequent and growing cause of troubles of sight).

Dr. Lee said defective ventilation and late hours (especially after dark) were undoubted causative agents in this connection. The subject of school hygiene is now engaging the attention of the school board, and he also recently heard it discussed in London. In Maryland the hours and amount of work required exceed those in any other State. Some of our school-buildings are defective, and two or three should be pulled down.

Dr. I. E. Atkinson did not think any fault was to be found with the hours; the trouble is due to a want of correct scientific knowledge on the part of those who have charge of the pupils. Sufficient attention was not paid to the proper arrangement of the light (so that, for instance, it would not dazzle), to the character of the books, ventilation, etc.

Dr. A. F. Erich said impure air, as a cause of headache, was not sufficiently appreciated. The judgment of the teacher might obviate the bad effects of insufficient light, those studies requiring but little light being put off until the late hours.

Dr. Arnold said children were almost exempt from neuralgia, while hemicrania is far from uncommon in this class of patients. The evils of going to school cannot be entirely gotten rid of; it is an unnatural state for children to be compelled to sit quiet on benches poring over books. He referred to the fact that the brain-substance is insensible, and that any pain must be referred to the membranes covering it, which are supplied with sensory branches from the trifacial.

PATIENT WITH OBSCURE SWELLING OF LEFT SHOULDER AND ARM.

Dr. R. B. Morison presented a negro drayman, aged thirty-three years, with the following history: Four or five years ago a swelling appeared in his left shoulder. Shortly after one of his fingers on the same side was frostbitten, and consequently was amputated. The swelling slowly increased, extending finally half-way down the arm. It was soft and œdematous, and not accompanied by pain. In summer the swelling in the arm subsided. The lower part of the arm was very much reduced. The

fluid was aspirated and found to be nearly pure serum. The swelling afterward broke opposite the middle of the arm, and has continued to discharge serum and fat ever since. Into the natural opening thus formed a probe was passed up toward the shoulder a distance of five inches. There was no specific history in the case—no cancer-cells to be discovered on microscopic examination. The patient exhibited a cardiac anæmic murmur, for which he was taking iron and digitalis. He had been compelled to give up work. Opinions were requested as to the diagnosis of the case.

Dr. I. E. Atkinson regarded the swelling as due to enlargement of the lymph-channels from obstruction caused, doubless, by the protracted inflammation—a condition comparable to elephantiasis or Barbadoes leg. A negro girl had an enlargement of the right labium to the size of a double fist. The swelling was due to fluid which was not simply beneath the epidermis, but deeper down. One of the sacs containing the fluid being incised, gave exit to lymph. The labium was strapped as in treating orchitis, with the result of the almost entire disappearance of the swelling, which returned, however, on the cessation of the pressure.

Dr. L. McL. Tiffany regarded it as a case of enlargement of the lymph-channels from previous lymphangitis. The probe mentioned had passed up by the long tendon of the biceps muscle, and would, no doubt, have passed up twelve or eighteen inches if it had been of sufficient length. The fat in the discharge shows that the fistula passes through connective tissue. A swelling under the acromion, as here, is almost always connected with the joint. An examination in the axilla shows the presence there of three small bony growths, two behind and one below the joint. He knew of no other condition which could cause such growths but malignant disease.

A colored boy suffered a dislocation of the arm at the age of fourteen years. After reduction, a swelling formed about the joint, which on opening gave exit to a pint of pus. The patient remained well for two or three years, when the swelling gradually returned: an incision was made into which the finger was introduced, and about a pint of medullary (cancerous) matter removed. Simple inflammation is not capable of producing bony growths in the axilla, disconnected with the bony skeleton (as here). The course of events in the case before us seems to have been: 1st, some change about the joint interfering with the lymph-channels; 2d, malignant disease of the joint. It is certain that the symptoms in the case are due to joint-trouble.

GROWTHS IN THE LARYNX.

Dr. H. Clinton McSherry read a paper on this subject. Laryngeal growths were due, he said, to hyperæmia of the mucous membrane. Dr. B—— one year ago complained of sore throat and hoarseness, which, on examination, was found to be attributable to congestion of the larynx. Under treatment the voice returned. Four months later the trouble returned, and the right vocal cord was found congested. He improved under astringents. Five months later a small sessile growth was found, which was treated by the application of a strong solution of nitrate of silver; the growth increasing notwithstanding this treatment, the patient was advised to discontinue remedies entirely. The result has been that now, after three months, it is much smaller.

The second case related illustrated a local cause of hæmoptysis. The patient, a young man, had slight cough and spitting of blood in 1877. The heart and lungs were found to be free from any evidence of disease. On laryngoscopic examination, a pedunculated growth the size of a split-pea was discovered on the right vocal cord, on the surface of which was seen a small nutrient vessel. There was spasm here, and a possibility of the growth becoming detached and falling into the trachea. Hence it was extirpated with McKenzie's forceps, and Monsel's solution applied to the stump. The patient remains well after several years' interval, and has had no return of the hoarseness or hæmoptysis. If large, thyrotomy or laryngotomy may be demanded in such growths, and removal piecemeal. Billroth and others have even removed the entire larynx, but without success, except in one case occurring in Italy, in which the patient, after the lapse of three years, is able to do the work of a laborer in the field.

Laryngeal growths are not of rare occurrence, the only way to diagnose them is by the laryngoscope. The speaker impressed the idea that laryngeal growths do not always necessarily require removal; it may be best to leave them alone, unless by their size or symptoms they cause great trouble.

A third case was related, in which there was a growth on the vocal cords, accompanied by spitting of blood; but this was referable not to the growth, but to tubercular disease of the lungs, one of which showed a cavity, the other softening. Hoarseness should always lead to examination of the lungs.

SARCOMATOUS TESTICLE.

Dr. J. E. Michael exhibited a sarcomatous testicle which he had removed from a man, forty-two years of age, otherwise in perfect health. There was no glandular enlargement, and no secondary growths to be discovered.

CASE OF SINGLE KIDNEY.

Drs. Fenby and Walker exhibited an enlarged kidney, weighing 9¼ oz., obtained in a post-mortem made in connection with a coroner's inquest. It occupied the left side. Careful examination failed to reveal any sign of the other kidney.

INTRACRANIAL ABSCESS.

Dr. Herbert Harlan exhibited a specimen obtained from a stone-mason, thirty-five years of age, who came to the University Clinic suffering with violent facial neuralgia of the left side, of six months' duration, with slight protrusion of the corresponding eye-ball. There was a history of syphilis in the case. A diagnosis of intracranial tumor, probably syphilitic, was made, and the patient was put upon iodide of potash. He gradually grew worse, and died while in a comatose condition, seven days after he was first seen. None of the senses were impaired, nor was there any paralysis except ptosis of the left upper lid.

Post-mortem.—Adhesion of the brain in the middle fossa of the skull. One drachm of pus was found beneath the dura mater, at the root of the great wing of the sphenoid bone, extending slightly into the sphenoidal fissure; the bone was slightly eroded in the same situation. The cranial nerves were unaffected. There was a small abscess on the inferior convolution of the spheno-temporal lobe of the left side, from which pus had flowed into the lateral ventricle. It had passed thence through the foramen of Monro into the third ventricle, from thence into

the fourth ventricle, and finally out, to be diffused over the surface of the pons and cerebellum. The immediate cause of death was, doubtless, the passage of the pus into the fourth ventricle. The disease originated, he thought, in the dura mater. There was an ulcer on the septum nasi, in the left nostril —non-specific, it was supposed.

THERAPEUTIC VALUE OF TARTAR-EMETIC.

Dr. A. B. Arnold read a paper upon this subject. He said a great change had taken place in its estimation. First employed in fevers and then lauded in pneumonia by Lænnec and others, we find now leading German pathologists (Nothnagel, etc.) maintaining that it is almost useless in any disease. Even Bartholow confines its use to catarrh of the air-passages. So far as its antipyretic and relaxing effects are concerned, they are better procured by other remedies now at our command. But we have no better remedy to counteract inflammation of the larynx and trachea. In inflammatory croup it is capable, if early used, of keeping it in the catarrhal stage, and preventing its passage into the membranous form. He would give in this case $\frac{1}{12}$ grain every hour to a child. In one case, at six years, he gave $\frac{1}{4}$ grain every hour, with excellent results.

Dr. I. E. Atkinson agreed with Dr. Arnold in thinking that great injury is done by dispensing with such a useful remedy. In catarrhal and croupous troubles he had obtained most satisfactory results from it (in the form of hive syrup). He had also seen beneficial results from it in acute pleurisy.

Dr. A. F. Erich limits its use to croup (in which he precedes the hive syrup by the yellow sulphate of mercury), and to hoarseness.

Correspondence.

THE ETIOLOGY OF LEPROSY.

To the Editor of The Medical Record.

Sir—In an article by Jonathan Hutchinson, Esq., F.R.S., on the etiology of true leprosy, recently published in the *Medical Press and Circular*, he says: "We find that nearly everywhere the disease is most common on the sea shore, and that when it spreads inland it generally occurs on the shores of lakes, or along the course of large rivers; we find, also, that fish is largely eaten when leprosy prevails." He continues: "I don't believe that any other article of diet has any influence whatever on the causation of the disease; this is so special in its character that it must have one special cause."

In confirmation of this opinion, I will state my experience, acquired while on a visit three years ago to the north shore of New Brunswick, Dominion of Canada. Here leprosy has prevailed more or less since its early settlement by the French, having been brought over with them.

At the village of Tracadie a lazaretto has been established for several years, and is under the charge of the Sisters of Charity of Montreal, and at the time of my visit contained twenty-nine inmates in various stages of the disease.

Upon inquiry I learned that there was no regular medical attendant connected with the institution, but that the nuns prescribed and dispensed the medicines themselves under some general instruction. In conversation with one of the trustees, a very intelligent gentleman, I learned that the inhabitants were very poor, and that the disease was confined to the descendants of the French, living almost exclusively on fish and potatoes, preferring the former in a state of decomposition, or as he expressed it, putrid, having acquired a taste for it similar to that of the English for high pheasant. I also learned that cancer is a very common disease among these poor people.

Arnold Hallett, M.D.,
Late Physician to Long Island College Hospital.

LEPROSY AND HOÀNG-NÀN.

To the Editor of The Medical Record.

Sir—I have been permitted to read and to make extracts from a letter addressed to Messrs. Parke, Davis & Co., of Detroit, by *frère* Etienne Brosse, of Cocorite, author of "La lépre est contagieuse." These extracts I offer as a supplement to the paper recently read by me at the Academy of Medicine (Medical Record, February 19, 1881). The letter is dated January 27, 1881. Speaking of the use of hoàng-nàn in leprosy, the writer says: "I continue to use it constantly, and the results are the same. As yet there have been no complete cures, but almost always remarkable amelioration, and I have patients in whom all symptoms have disappeared so completely that their own families did not suspect the existence of the disease. . . . . The fact of the contagious character of leprosy should result in legislation providing for the isolation of these patients.

"America is interested in this, for, without speaking of the Norwegians, who have carried the disease into their settlements, the Chinese have introduced it into California, and there is not the shadow of a doubt but that it will pass from them to the other inhabitants of the country. Thus far it has been confined to the Chinese, but it certainly will not be restricted to them.

"Besides its use in leprosy, hoàng nàn has been employed in other affections, as hydrophobia, syphilis, scrofula, ulcers, and fevers. In hydrophobia I have no experience with it; one of my leprous patients contracted syphilis, and the effect of the remedy was surprising. It is highly recommended in scrofula. In this affection I have not tried it. I have given the remedy to two children attacked with 'yaws' and they were promptly cured. The ulcers of leprosy, when not too far advanced, cicatrize promptly, and it is probable that other ulcers would be benefited. All of my lepers, without exception, have been cured of the fever.* I have also used it with the same success in intermittent fever. I personally suffered for eight years from attacks of fever, which increased in frequency and intensity until four years ago, when I commenced using hoàng-nàn. Since then the fever has frequently exhibited its precursory symptoms, which have yielded immediately to the drug. It is far more valuable in fever than quinine.

"Another useful application is as a stimulant in prolonged intellectual work. Dr. Eklund, of Sweden, has written me: 'A thousand persons bless your remedy. As for myself, I work twelve and fifteen hours continuously without fatigue.' Hoàng-nàn may be taken for a long time without inconvenience, and, in fact, with benefit to the general health. While making these statements, it must be remembered

* The writer neglects to note the special kind of fever.

that I am not a physician, but a missionary,* and am unable to speak with proper scientific detail, but simply relate my personal experiences and observations.

"It was first announced that hoàng-nàn should be employed in combination with realgar and alum. For a long time I so used it, but am now satisfied that it is better to give it pure in three-grain pills: one pill every morning before breakfast, increased sometimes by a second or third pill at intervals during the day. It may thus be continued indefinitely. In an appropriate dose it is laxative; in too strong dose the contrary effect is produced. The patient should not use spirits or stimulating food.

"Chemical analysis has revealed the presence of brucia and strychnia in hoàng-nàn, the first existing in larger quantity than the second."

The foregoing extracts are not literal translations, but a somewhat condensed statement from *frère* Etienne's letter. It is hardly to be expected that the drug will prove as valuable as the writer of the letter appears to believe, but it is certainly one that should be made the subject of careful study and experiment. Hoàng-nàn is the powdered bark of the Strychnos Gautheriana, *Pierre*, and adds another member to the small group of analogous drugs now in use. Resembling nux vomica and ignatia in its active constituents, it differs from them as they do from each other in the proportional quantities in which they are found. According to Flückiger and Hanbury, nux vomica contains 0.25 to 0.5 per cent. of strychnia, and 0.12 (Merck), 0.5 (Wittstein), 1.01 per cent. (Mayer) of brucia, while ignatia contains 1.5 per cent. of strychnia and 0.5 per cent. of brucia, while hoàng-nàn, it is stated, contains more brucia than strychnia.

Respectfully yours,
HENRY G. PIFFARD, M.D.

THE ADVANTAGES OF THE METRIC SYSTEM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR,—Notwithstanding Dr. Stair's assertion of the great superiority of this nation, there is a vague impression entertained by some that even we can learn. As the doctor objects to a system however perfect, because of its foreign origin, perhaps he will suggest one himself, as he would hardly maintain that the heterogeneous collection of weights and measures in use among us now is American in any sense except by naturalization. We have borrowed from England a system as inconvenient as it could well be, and without the least logical connection between its several parts, with no reason for its existence except custom. Yet if we talk of borrowing from France a system so simple and logical that any person of ordinary intelligence can, in a few minutes time, learn the rules by which he can construct the tables for himself from the unit of linear measure (which is the foundation of the whole system), we are met with the reproach of weakly following foreign lead, as well as of trying to gain a cheap reputation for linguistic attainments.

As to the latter charge, it is not easy to understand how metre is any more foreign when applied to measure of length, than when applied to the number of feet in a verse in prosody; and as for the prefixes milli, deci, and centi, we use them every day in words that no one considers foreign. Gram, is no more formidable than dram, nor is fluigram any harder to pronounce than fluiddram, and yet these are all the words and prefixes essential to be adopted. As a mere matter of prescribing, the metric system would have the especial advantage over the troy weights, of greater facility in calculating the percentage of the active ingredients necessary in a mixture to make the proper dose in a given quantity. But it is when we compare the two systems as a whole that the simplicity and logical connection of the French system serves to bring out more clearly the complexity, awkwardness, and want of logical sequence in the English. In fact, the latter is not properly a system at all, but simply a collection of different weights and measures which were in use in different parts of England at the time when an attempt was made to put them on a scientific basis. A standard pendulum is obtained in a scientific manner it is true, but instead of making this the unit of a system, a unit is taken that bears an inconvenient ratio to this standard. The wine gallon is decreed to contain two hundred and thirty-one cubic inches, but by what rule could such a relationship to the standard yard be established. Again, by what possible rule could the standard pounds, either one, be obtained from the yard. In short, the whole collection is so full of absurdities as to be apparent to every one, were it not that we are accustomed to them.

Although it goes by saying that the progression of these tables should be in accordance with our arithmetical notation, yet nowhere in the English tables is this decimal progression used.

Compare this system, or rather want of system, with the metric. Starting from the standard metre and the unit of measures of capacity arises out of it by cubing one-tenth of the metre. Cube the one-hundredth part of a metre, and you have the measure of the quantity of distilled water at maximum density that weighs one gram, which gives the unit of weight. Here is the whole system in a nutshell, *simplex munditiis*, but this is foreign. Given in addition to this that these units are divided and multiplied decimally, and you have a system as simple and complete as that of Federal money, and I hardly think that Dr. Stair would wish to change back to English money, although he likes English weights and measures so well.

In order to overcome some of the inconveniences of the English table of linear measure, engineers have founded on it a table of their own, the unit of which is a chain, usually four rods long, but sometimes one hundred feet, divided in either case into one hundred links. How much more convenient the metre and its derivatives, especially in extensive geodetic operations like those of the U. S. Coast Survey, in which the relation of the metre to a great circle of the earth would save much computation!

It may be said that such considerations as these have no bearing on the introduction of the metric system into medicine, but those who study the matter at all study it as a whole, and seek for the introduction of the system as a whole, and when it is introduced, as it surely will be, Dr. Stair can comfort himself with the reflection that the system, though foreign, has simply supplanted another system, also foreign. But, after all, perhaps the most comforting consideration is that true science is of no country, but is like light, universal.

Yours truly,
J. H. CHURCHILL, M.D.

CROSS RIVER, N. Y., February 26, 1881.

* Attached to a leprosery.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 27, 1881, to March 5, 1881.

By Wm. H. Arthur, Geo. E. Bushnell, H. P. Bermingham, and M. C. Wyeth, appointed Assistant Surgeons U. S. Army, to rank from February 18, 1881.

War Department, Surgeon-General's Office, Washington, February 25, 1881.

The Death of Geo. A. Otis, Surgeon and Brevet Lieutenant-Colonel, U. S. Army.—It is with profound regret and a sense of loss, not only to his corps, but to the medical profession, that the death of George Alexander Otis, Surgeon and Brevet Lieutenant-Colonel, U. S. Army, is announced to the medical corps of the army.

Born at Boston, Massachusetts, November 12, 1830, he graduated with the degrees of A.B. and A.M. from Princeton College; entered the Medical Department of the University of Pennsylvania, and received his degree of M.D. from that institution in 1850; visited Europe, and prosecuted his studies in London and Paris, and returning to this country he established himself at Springfield, Mass.; appointed Surgeon 27th Massachusetts Volunteers, September, 1861, he held this position until appointed Surgeon, U. S. Volunteers, August 30, 1864. After the close of the war he entered the Medical Corps, U. S. Army, as Assistant Surgeon, February 28, 1866; became Captain and Assistant Surgeon, July 28, 1866; Major and Surgeon, March 17, 1880, having received the four brevets of Lieutenant-Colonel of Volunteers, Captain, Major, and Lieutenant-Colonel, U. S. Army, for meritorious services during the war. While Surgeon of the 27th Massachusetts Volunteers he served in Virginia, North and South Carolina, and was on special duty in charge of the hospital steamer Cosmopolitan, in the Department of the South. Assigned to duty in this office July 22, 1864, he was curator of the Army Medical Museum, and in charge of the Division of Surgical Records until his death.

He was editor of the Richmond *Medical Journal* for three years, member of the leading medical societies of America, and corresponding member of various similar societies in Europe, and a contributor to prominent medical journals. Surgeon Otis, with his personal observations of the surgical collections abroad, brought indefatigable industry and untiring energy to the development of the surgical and anatomical collections of the Army Medical Museum, which he has made the most valuable of their kind in the world. The compilation of the "Surgical Volumes of the Medical and Surgical History of the War" has placed Surgeon Otis confessedly among the most prominent contributors to surgical history.

While on duty in this office Surgeon Otis wrote for publication no less than ten reports on subjects connected with military surgery, etc.; among which are his most valuable and exhaustive reports on "Excision of the Head of the Femur for Gunshot Injury," and on "Amputation at the Hip-joint in Military Surgery." Of great culture, retentive memory, and with a remarkable facility of expression, he was, as a compiler and writer, conscientious in his analyses, giving his deductions from the facts before him with modesty, but decision. With such a record it is needless to speak of his zeal, his ambition, or his devotion to his profession, and especially to the reputation of the corps of which he was so bright an ornament. While devoting himself to the preparation of the third and last "Surgical Volume (now more than half completed) of the Medical and Surgical History of the War," he died in this city February 23, 1881. His untimely death will be deeply deplored, not only by the medical corps of the army, but by the whole medical profession at home and abroad.

Jos. K. Barnes,
Surgeon-General.
